CLINICAL LABORATORY METHODS AND DIAGNOSIS

A textbook on laboratory procedures and their interpretation

Edited by

SAM FRANKEL, Ph.D.

Director of the Division of Biochemistry, Department of Laboratories,
The Jewish Hospital of St. Louis, St. Louis, Mo.; Member, American Association of
Clinical Chemists and American Chemical Society

STANLEY REITMAN, M.D.

Director of the Gradwohl Laboratories and the Gradwohl School of
Laboratory Technique, St. Louis, Mo.; Member, Teaching Staff,
Department of Medicine, The Jewish Hospital of St. Louis, St. Louis, Mo.; Editor-in-chief,
The Laboratory Digest; Member, American Public Health Association, Royal Society
of Health (London), American Society for Microbiology, and American
Society of Tropical Medicine and Hygiene

Associate Editor of Microbiology

ALEX C. SONNENWIRTH, Ph.D.

Director, Division of Microbiology, Department of Laboratories, The Jewish Hospital of
St. Louis, St. Louis, Mo.; Assistant Professor, Department of Microbiology,
Washington University School of Medicine, St. Louis, Mo.; Member, American Society for
Microbiology, American Association of Blood Banks, and American Association

Contributors

PHILIP G. ACKERMANN, Ph.D. Protein-bound iodine; blood lipids
Research Assistant Professor, Division of Gerontology, Washington University School of Medicine, St. Louis, Mo.; Chief Biochemist, St. Louis Chronic Hospital, St. Louis, Mo.

JOHN D. BAUER, M.D. Hematology; spinal fluid
Director of Laboratories, DePaul Hospital and Faith Hospital, St. Louis, Mo.; Assistant Professor in Pathology, Washington University School of Medicine, St. Louis, Mo.

EVERETT S. BENEKE, Ph.D. Medical mycology
Professor in Mycology, Biology Research Center, Michigan State University, East Lansing, Mich.

M. R. CASTAÑEDA, M.D. Brucella
Director, Investigaciones Medicas, Hospital General, Mexico, D. F.

W. HAROLD CIVIN, M.D. Model of a clinical laboratory
Director of Laboratories, The Queen's Hospital, Honolulu, Hawaii

NORMAN E. DEWAR, Ph.D. Disinfectants, sanitizers, and antiseptics
Director of Research, Vestal Laboratories Inc., St. Louis, Mo.

JULIUS ELSON, M.D., F.A.C.P., F.A.C.C. Electrocardiography
Instructor in Clinical Medicine, Washington University School of Medicine, St. Louis, Mo.; Assistant Physician, Barnes Hospital, St. Louis, Mo.; Attending Physician, Teaching section of Medical Staff, The Jewish Hospital of St. Louis, St. Louis, Mo.; Chief, Department of Medicine, Christian Hospital, St. Louis, Mo.; Cardiologist to Christian Hospital, St. Louis, Mo.

ADDINE G. ERSKINE Blood groups
Principal, Gradwohl School of Laboratory Technique, St. Louis, Mo.; Assistant Editor, The Laboratory Digest

SAM FRANKEL, Ph.D. Clinical chemistry; urinalysis; gastric secretion and duodenal content
Director, Division of Biochemistry, Department of Laboratories, The Jewish Hospital of St. Louis, St. Louis, Mo.

M. L. GRAY, Ph.D. Listeria monocytogenes
Associate Bacteriologist, Veterinary Research Laboratory, Montana State College, Bozeman, Mont.

LEWIS J. GRIFFITH, Ph.D. Bacterial sensitivity testing

Acting Chief, Clinical Laboratories, and Chief, Staphylococcus Reference Laboratory, Veterans Administration Hospital, Batavia, N. Y.; Instructor in Bacteriology, University of Rochester School of Medicine and Dentistry, Rochester, N. Y.

MICHAEL H. IVEY, Ph.D. Parasitology

Assistant Professor, Department of Microbiology, University of Missouri School of Medicine, Columbia, Mo.

J. MEHSEN JOSEPH, Ph.D. Viral and rickettsial diagnostic procedures

Chief, Division of Virology, Bioanalysis and Training, Bureau of Laboratories, Maryland Department of Health, Baltimore, Md.; Instructor in Microbiology, University of Maryland, Baltimore, Md.

SIDNEY KAYE, Ph.D. Toxicology

Professor of Toxicology, Department of Pathology, School of Medicine, San Juan, Puerto Rico; formerly Toxicologist, Office of the Chief Medical Examiner, Commonwealth of Virginia, and Director, Poison Control Centers, Richmond, Va.

GERALD KESSLER, Ph.D. An automated system of analysis

Supervising Biochemist, Division of Neoplastic Medicine and Clinical Research Center, Montefiore Hospital, New York, N. Y.

TAKESHI KODAMA, M.D. Streptococci

Director, Kanagawa Prefectural Public Health Laboratory, and Chairman, Japanese Association of Public Health Laboratories, Yokohama, Japan

†ARAM A. KRAJIAN, Sc.D. Tissue cutting and staining

Formerly of Department of Histopathology, Los Angeles County Hospital, Los Angeles, Calif.

HARRY W. MARGRAF Hormone assay in clinical diagnosis

Research Instructor, Washington University School of Medicine, St. Louis, Mo.

SACHIMOHAN MUKERJEE, M.B., D.Phil. Bacteriophage

Head, Division of Microbiology, Indian Institute for Biochemistry and Experimental Medicine, Calcutta, India.

ERWIN NETER, M.D. Bacterial hemagglutination

Director of Bacteriology, Children's Hospital, Buffalo, N. Y.; Associate Professor of Bacteriology and Pediatrics, State University of New York at Buffalo Medical School, and Research Professor of Microbiology, State University of New York at Buffalo Graduate School, Roswell Park Division, Buffalo, N. Y.

†G. PANJA, D.Bact.(Lond.), F.N.I., F.D.S.(Lond.) Vibrio comma

Professor of Bacteriology and Pathology (retired), School of Tropical Medicine, Calcutta, India.

†Deceased.

New England Institute for Medical Research, Ridgefield, Conn.

STANLEY REITMAN, M.D. The microscope; basal metabolism; gastric secretion and duodenal content; feces

Medical Director, Gradwohl School of Laboratory Technique, St. Louis, Mo.; Editor-in-Chief, The Laboratory Digest; Teaching Staff, The Jewish Hospital of St. Louis, St. Louis, Mo.

ALVIN L. ROGERS, B.S. Medical mycology

Research Associate, Biology Research Center, Michigan State University, East Lansing, Mich.

A. CHARLOTTE RUYS, M.D. Leptospira

Professor in Bacteriology, Immunology, and Epidemiology, University of Amsterdam, The Netherlands.

ALEX C. SONNENWIRTH, Ph.D. Clinical bacteriology; serology

Director, Division of Microbiology, Department of Laboratories, The Jewish Hospital of St. Louis, St. Louis, Mo.; Assistant Professor, Department of Microbiology, Washington University School of Medicine, St. Louis, Mo.

MAURICE S. TARSHIS, Ph.D., F.A.P.H.A. Mycobacteria; nocardia

Director, Tuberculosis Research, Medical Research Laboratory, Veterans Administration Hospital, Alexandria, La.; Member, Committee on Pathology and Microbiology, American College of Chest Physicians

GELSON TORO, Ph.D. Protein-bound iodine; blood lipids

Assistant Director of Scientific Research, The Gerontological Research Foundation, St. Louis, Mo.; Consultant in Biochemistry, St. Louis Chronic Hospital and Missouri Clinical and Biochemical Laboratory, St. Louis, Mo.

In memoriam

Rutherford Birchard Hayes Gradwohl, M.D., Sc.D.

MARCH 4, 1877—MAY 9, 1959

May 9, 1959, marked the end of a professional life of sixty years devoted to the practice of medicine and to its advancement as a science. Dr. Gradwohl's career reflected a diversity of interests, the eagerness to investigate new fields of knowledge, and the spirit of inquiry and enthusiasm that marked him as a person. Born in Baltimore, Maryland, the seventh son of a seventh son, Dr. Gradwohl was educated in the public schools and in 1898 was graduated in medicine from Washington University School of Medicine, St. Louis, Missouri, later serving his internship at St. Louis City Hospital. He began the first of a series of postgraduate studies in Europe in 1900 where, under the guidance of Professor Langerhans and Dr. Rudolf Virchow, he entered the field of pathology, which was to become the major interest of his life. He studied for a year in Paris at the Pasteur Institute, returning home to accept a position as Professor of Bacteriology and Pathology at the Marion Sims–Beaumont Medical School, later to become the St. Louis University School of Medicine.

While serving as autopsy physician for the coroner of the City of St. Louis, he became interested in legal medicine and later, in 1934, along with Captain Elias Hoagland, was instrumental in establishing the Crime Laboratory of the St. Louis Police Department. This interest in legal medicine led, at the age of 72 years, to his founding and becoming the first president of the American Academy of Forensic Sciences, which held its first meeting in Chicago on January 26-28, 1949. From the establishment of the Crime Laboratory at the St. Louis Police Department until his death, Dr. Gradwohl was director of that laboratory. Under his guidance, it became one of the most complete police laboratories in the country.

Clinical Laboratory Methods and Diagnosis became a major contribution to the literature of the laboratory when it appeared in its first edition in 1936 as a one-volume text. During Dr. Gradwohl's lifetime, the textbook appeared in five editions. Many of the present contributors had collaborated with him in his writings. In addition to this text, Dr. Gradwohl wrote, in 1917, what was probably the first book in the English language on blood and urine chemistry and later, in 1932, published his own book entitled *Laboratory Technique,* assisted by his wife, Ida Emmons Gradwohl, and his niece, Addine Gradwohl. In 1929 he translated Schilling's *Das Blutbild (The Blood Picture)* from German into English. He is known also for his textbooks *Clinical Tropical Medicine* and *Legal Medicine.*

Dr. Gradwohl became interested in the work of Landsteiner and Wiener on the Rh factor and in 1939 and 1940 studied under their direction, introducing their work in his many monographs and lectures. In 1948 he enrolled at Cornell University to study exfoliative cytology under Dr. George Papanicolaou and introduced the latter's test in St. Louis and elsewhere.

In 1937 he established *The Laboratory Digest,* a monthly review of clinical laboratory literature, which has continued publication since that time.

A Commander in the United States Naval Reserve, he served first as Lieutenant Commander in 1917, assembling a Navy Hospital Unit in St. Louis consisting of a surgeon, an internist, a radiologist, a laboratory technologist, and an oculist. He was later transferred to the Naval Hospital and Training Station in New Orleans, Louisiana. He served in the Reserve until his retirement in 1940. One of his first suggestions to the Surgeon General was made in about 1932, urging the recruitment of a highly trained specialist reserve corps, with units in each medical center. Early in the 1930's he had suggested to the Surgeon General that a radical change be made in personnel records, namely, that the blood group and type of each individual be tested and the results included on health records and identification disks. This was adopted and is still in effect.

With a knowledge of German, French, Spanish, and Italian, as well as English, Dr. Gradwohl was able to utilize much of the technical medical literature of the Western World, and this information was passed on to his students at the school he had founded in 1920, as well as to those who used his textbooks and read his monographs.

He was a Fellow of the Royal Society of Tropical Medicine and Hygiene (London), a Member of the Royal Society of Health (London), a Fellow of the American Public Health Association, a Fellow of the American Urological Association, and for many years a Fellow of the American Medical Association. He became an honor member of the Sociedad Cubana de Policiologia y Criminalistica in 1949 and others too numerous to mention. His last two honors came in 1958, when he was unanimously elected foreign corresponding member of the Society of Legal Medicine and Criminology of France and the German Association of Legal Medicine.

Dr. Gradwohl was Pathologist to Christian Hospital in St. Louis from October, 1925, to the date of his death. He was Pathologist to the St. Louis County Hospital from October, 1933, to April, 1937. He has been referred to as the "dean of American legal medicine" and the "father of forensic pathology" in this country. In 1954 he received an award from the American Academy of Forensic Sciences for his outstanding work in legal medicine.

With his many achievements in numerous fields, Dr. Gradwohl will always be remembered for his work in the clinical laboratory, primarily as a teacher of laboratory methods. As Dr. Alexander S. Wiener has stated, "Because of his encyclopedic *Clinical Laboratory Methods,* he has left a permanent heritage in those workers who have used his books and who have studied in his school. As Founder of the American Academy of Forensic Sciences he has also made an invaluable and permanent contribution to that field."*

A. G. E.

*The Laboratory Digest, Special Issue, June, 1959.

With love to
Dodo, Marsha, and Scott Frankel
Helene, Laurie, and Laurence Reitman
and
Rosaline, Maurice, and Betty Sonnenwirth
we dedicate this book

Preface

The sixth edition of *Gradwohl's Clinical Laboratory Methods and Diagnosis* has been essentially rewritten, but Dr. Gradwohl's original purpose, that this work serve as a reference source, textbook, and laboratory manual, has been retained. We have therefore included general discussions, detailed instructions of procedures, and information pertinent to the interpretation of results, as well as an extensive bibliography.

The contributions of twenty-nine individuals have permitted the editors to obtain authoritative coverage of the vast field of laboratory medicine. There was surprising agreement among the experts concerning topics common to two or more fields. When, however, different schools of thought were represented, we attempted to adequately present both points of view.

The section on Clinical Chemistry has been arranged so that each chapter contains material according to category. It is impossible, of course, to have a system that completely avoids overlapping material. A typical example is the test for alkaline phosphatase activity, which is considered to be of value in the investigation of liver function but which also falls into the category of enzymes.

The entire discussion on colorimetry has been drastically shortened and emphasis has been shifted to calibration technics. Where visual colorimetry is described as the means for assay, conversion calculations are shown so that the procedure may be transferred to the photoelectric colorimeter with little or no change in methodology. This is done as a compromise so that those laboratories that are still using a visual colorimeter, and there are many, may either continue to use the procedure or, if desired, convert to the more modern method.

A good deal of material from the fifth edition has been omitted to make available the space required for new material. The decision as to which of the procedures to delete, however, was a most difficult problem. Two sources of information were used in evaluating the requirements of laboratories: data from a survey sent to several hundred laboratories plus an examination of the records of chemistry tests performed at The Jewish Hospital of St. Louis.

The results of the survey were most interesting and yielded considerable information pertinent to this problem of deciding which material to retain, delete, expand, or shorten. One example of the manner in which the information was used may be seen from the results concerning methods for performing urea nitrogen assays. Only 2.8% of the laboratories responding to the survey used the aeration method, compared with 75% using urease followed by direct nesslerization and 16% using diacetylmonoxime. The critical need for space was such that the relatively large discussion on the aeration method had to be omitted. Other deletions were decided in a similar manner.

In certain cases, procedures were exchanged. A typical example of this is found in the discussion of flame photometry. This edition describes the procedure employing the Coleman Flame Photometer which is used in 84% of the laboratories responding to the survey, whereas only 11% were using the Beckman method described in the fifth edition.

Several procedures, either new or new to this edition, are included, as well as modifications of many standard methods. This again was decided partly on the basis of the survey results. The discussion of paper electrophoresis was considerably expanded. Two additional glucose assays, both yielding "true glucose" results, have been added. Two methods for uric acid, one new and one not so new, have been included. Enzymology has been greatly expanded, consistent with the current trend. In addition, several tests have been incorporated for the assay of serum iron, iron-binding capacity, tubular reabsorption of phosphorus, sweat chlorides, and many others to bring the text up to date.

One more important factor must be considered. Although it may appear incongruous to retain old material at the expense of excluding new procedures, a little reflection on the matter will justify this decision. Procedures that have been used for several years, the weaknesses having been corrected by numerous modifications during extensive experience, are known to all as to their usefulness and their limitations. The new ones, however, have not yet stood the test of time and are still of unknown value. It is for this reason that some of the old classical material remains, perhaps slightly modified, but essentially unchanged.

Perhaps the most significant advances have been in the area of lipids, protein-bound iodine, steroids, and automation, all of which have become extremely important in modern clinical chemistry. In each case, these subjects have been treated by authorities in the field.

Protein-bound iodine has been completely rewritten by investigators who have had an enormous amount of experience in this area (Toro and Ackermann). All acceptable procedures for the assay of protein-bound iodine, including comments concerning advantages and disadvantages, have been included.

The same contributors have submitted the material on lipids, including cholesterol, a field that has been the basis of their research for many years.

Hormone assays have been compiled into a single chapter which includes certain of the pregnancy tests (Margraf).

The chapter on automation (Kessler), impossible to include in detail in a reasonable amount of space, nevertheless offers a sound introduction to an area of laboratory technic which is undoubtedly one of the focal points of all future progress in the clinical laboratory.

The section on Toxicology (Kaye) has been thoroughly rewritten so that emphasis has been placed on the most modern methods. Included are discussions of tests and actual cases which exemplify the information presented in the text. This is, without question, the most complete collection of data on toxicology to be found in any general laboratory text.

Part III, Microbiology, was almost completely rewritten, reflecting the considerable array of changes in methodology, nomenclature, and materials that have taken place since the last edition of this book. It now consists of five sections: Bacteriology, Serology, Viral and Rickettsial Diagnostic Procedures, Medical Parasitology, and Medical Mycology.

The Bacteriology section is the result of the efforts of several contributors (some of whom were originally recruited by Dr. Oscar Felsenfeld).

The nomenclature and classification of bacteria used here, with some exceptions indicated in the text, are based on the seventh edition of *Bergey's Manual of Determinative Bacteriology*. The methods and procedures selected and described, new and old, are those that proved useful and reliable in the hands of many competent workers and which, in some cases, were originated by the contributors. In addition, alternate methods are described, which, where applicable, allow for flexibility with regards to available manpower, materials, and laboratory space.

The chapters on special methods, stains and staining procedures, and media, tests, and reagents (Sonnenwirth) include considerable new material on anaerobic technics, fluorescent antibody methods, maintenance of cultures, vaccine preparation, many useful newer media and, wherever available, recommended standard methods for staining and physiologic and biochemical tests. The chapter on collection and culture of specimens and guides for bacterial identification (Sonnenwirth) encompasses recommended procedures for the collection and examination of specimens and details of the media and methods to be used for primary cultures of specimens from various sources. It also includes the examination of primary cultures and describes, with the aid of various guides, preliminary steps for the identification of various bacteria.

A large number of newer methods were incorporated in the procedures for identification, such as the bacitracin and fluorescent antibody technics for group A streptococci, the use of Tinsdale medium for *Corynebacterium diphtheriae* and *Corynebacterium ulcerans*, and the methods recommended by the Communicable Disease Center, United States Public Health Service, for cultivation and identification of *Neisseria gonorrhoeae*. New technics for differentiation of *Actinomyces* and for identification of clostridia are also included.

A new feature is the outstanding discussion on *Listeria monocytogenes* (Gray), the important role of which is increasingly recognized in both human and animal infections.

The detailed and up-to-date contribution on mycobacteria (Tarshis) is, in the opinion of the editors, without parallel among contemporary textbooks. In particular, the discussion of unclassified mycobacteria and of the methods for determination of antituberculosis drugs in body fluids fulfills an important need.

The discussions of *Brucella* (Castañeda) and of *Vibrio comma* (Panja) were contributed by leading experts on the subject. New to this edition are detailed discussions on *Pseudomonas, Aeromonas, Serratia, Chromobacterium, Alcaligenes, Flavobacterium, Mimeae, B. anitratum, Spirillum,* and *Bacteroides* (Sonnenwirth).

The discussion of Enterobacteriaceae was completely revise and it now incorporates the new taxonomic schema and methods of P. R. Edwards and W. H. Ewing (Communicable Disease Center, United States Public Health Service). The sections on *Leptospira* and PPLO were completely revised and updated (Ruys). Dark-field microscopy, as used and recommended by the Venereal Disease Research Laboratory, Venereal Disease Branch, Communicable Disease Center, is incorporated in the material on *Treponema.*

Bacterial sensitivity testing is discussed in a completely new contribution (Griffith) which encompasses a description and critical evaluation of all presently used technics. Sanitary bacteriology now includes new procedures for the testing of disinfectants, sanitizers, and antiseptics (Dewar) and some technics useful in the prevention and investigation of hospital-acquired infections.

In view of the numerous advances in the serologic diagnosis of both infectious and other diseases, the section on Serology was considerably revised and enlarged. In the chapter on tests for syphilis, some older tests were eliminated, while the Reiter protein complement fixation test (RPCF), the fluorescent treponemal antibody test (FTA), and the rapid reagin tests (RPR and USR) were added. A unique contribution is the chapter on bacterial hemagglutination (Neter), not heretofore available in a textbook of this nature. The chapter on miscellaneous serologic tests describes the newer technics of gel diffusion, latex, and bentonite tests and includes discussions of serologic tests employed in the diagnosis of rheumatoid arthritis, the detection of thyroid antibody, and the lupus factor.

The great strides made in the laboratory diagnosis of viral diseases have been amply covered in the six chapters contained in the section on Viral and Rickettsial Diagnostic Procedures (Joseph).

In the chapter on classification and general consideration of viruses, considerable material on newer viruses, such as hemadsorption viruses, Sendai virus, Coe, JH, and 2060 viruses, reovirus, as well as newly described enteroviruses, is presented. A wealth of detailed information on technics is furnished in the chapter on tissue culture and chick embryo methods. Preparation of glassware, formulas of growth and maintenance media, and details for establishing continuous cell cultures are included. Detailed instructions for handling of specimens, the viral spectrum of host tissues, and various tests for typing (serum neutralization, hemadsorption) are described in the chapter on routine procedures for isolation and identification of viruses.

The serologic diagnosis of viral infections is described in great detail in a separate chapter. A most valuable addition is the chapter on cytologic and cytochemical technics for the study of viral infections. The last chapter of this section presents a review of rickettsiae and rickettsial diseases and describes methods for isolation and identification of rickettsiae and for serologic diagnosis of rickettsial diseases.

The section on Medical Parasitology has been completely rewritten (Ivey). Following a review of classification of animal parasites, methods of transmission and host-parasite relationships are discussed. Both protozoa and helminths are treated in detail, with geographic distribution, epidemiology, morphology, and laboratory diagnosis presented for each parasite.

Of invaluable aid will be the chapter on laboratory procedures in which both routine and specialized technical procedures are presented, including considerable new material. All reagents and solutions used are listed with instructions for preparation, followed by a description of technics for preservation, staining, and concentration of fecal specimens.

Among the new additions are the Valet, Weinstein, and Otto vital stain, the MIF fixative and stain, a modification of the Ritchie method, and the MIFC method. New details are described regarding the preservation and mounting of helminth adults and eggs. The section on cultivation methods of parasites has been enlarged.

The discussion of serologic and immunologic procedures includes a most complete description of recent procedures, such as the bentonite flocculation and latex agglutination tests for trichinosis, the Sabin-Feldman dye test for toxoplasmosis, and several others.

The section on Medical Mycology has been revised and updated (Beneke and Rogers). A concise chapter is devoted to the characteristics of true fungi, including structural details, modes of reproduction, and classification. The chapter on technics for the study of pathogenic fungi includes such newer procedures as the acridine orange fluorescent stain and the description of a slide culture method.

The information supplied in the chapter on mycoses includes, among others, newer media such as Trichophyton agars and growth patterns for the various species of *Trichophyton,* newly described species of *Microsporum,* and additional technics for the identification of *Candida albicans.* In addition, immunologic and serologic procedures applicable to the diagnosis of mycoses are discussed.

The section on Hematology (Bauer) contains a comprehensive treatment of this subject, including the latest material from the German literature as well as the American and English. The technics described have all been well tried and are presented in a step-by-step manner to increase the usefulness of the section. As in previous editions, much space is devoted to the description of the morphology and physiology of the cellular elements, enriched by remarks of their appearance in phase microscopy and electron microscopy.

A discussion dealing with human chromosomes (peripheral blood culture method) and sex chromosomes (peripheral blood smear method) is included.

In the material on the anemias, not only is the erythrokinetic approach stressed but also the biochemical and enzymatic defects, as well as the nonhematologic findings, such as aminoaciduria and bone and skin changes. Mention is made of vitamin B deficiency in blood diseases, of glucose-6-phosphatase activity and haptoglobins in hemolytic anemias, and of the amino acid pattern of hemoglobins. The discussion on macrocytic anemias includes the intermediate megaloblasts and mentions the determination of formiminoglutamic acid in folic acid deficiency as well as rare biochemical causes of macrocytic anemias, such as orotic acid excretion and inhibition of thymine synthesis.

The classification of porphyrias is based on clinical as well as biochemical criteria.

Discussions are included on such newer concepts as sideroachrestic anemias, myeloproliferative disorders, and functional platelet disorders.

The discussion of coagulation defects suggests a practical approach to their investigation by starting with simple basic tests, working up to more complex diagnostic procedures.

A chapter on the hematology of infants and children will be of particular value to the pediatrician and general practitioner. This special aspect of the subject is too frequently ignored.

The data from the fifth edition pertaining to normal blood findings in domesticated animals has been retained. This information is not usually found in a text of laboratory medicine, and its inclusion is another example of the completeness of this section.

The summary of changes in blood cellular elements and hemoglobin in various diseases is extremely valuable, presenting a mass of information in a concise, readily available form.

One of the outstanding contributions to the sixth edition is that on exfoliative cytology (Pharr). One of the most recent additions to the clinical laboratory, it has become an extremely valuable force in efforts to combat neoplastic diseases. This section gives the reader an excellent fundamental concept of the field and the specific technics employed.

The section on Blood Groups, Transfusion, and Medicolegal Applications (Erskine) has been completely rewritten. It has been critically read by both Dr. Lester J. Unger and Dr. Alexander S. Wiener, and their suggestions and corrections have been incorporated in the text. It is now probably the most complete discussion of the subject to appear in any general textbook on laboratory methods. The exact details of all methods of identifying blood factors and agglutinins are given, and these include the factors and antibodies in all the blood systems known at the time this section was prepared for publication.

A short résumé on the only known sex-linked blood group factor has been included to bring the material up to date. The International Nomenclature, as suggested by Wiener, is followed throughout, with a recapitulation of the English system of nomenclature. As suggested by the Committee on Medicolegal Problems of the American Medical Association, agglutinogens and phenotypes are printed in lightface type, blood factors and their corresponding antibodies in boldface, and genes and genotypes in italics. The latest approved methods of identification of common and rare blood factors are included, as are technics of cross-matching, posttransfusion reaction "work-up," isoimmunization, the nature of antibodies, tests for agglutinins in blood serum, titrations, and the "cross-reacting antibody" or anti-C of group O serum.

Other subject matter includes erythroblastosis fetalis, exchange transfusions, preparation of blood for transfusion, small units of blood, extracorporeal circulation, preparation of packed red blood cells, the choice of blood donors, untoward reactions to blood transfusions, the technic of whole blood transfusion, preservation of whole blood in the frozen state, the American Red Cross blood program, differential agglutination, prevention of hemolytic reactions, blood plasma as a substitute for whole blood in transfusion, plasma and serum fractions, platelet transfusions, pyrogens, dried plasma, the medicolegal aspects of blood grouping, including tests for exclusion of paternity, blood groups and heredity, blood groups and disputed maternity, the identification of blood stains, medicolegal aspects of blood transfusions, infectious diseases transmitted by transfusion, and other accidents following transfusion.

The section on Tissue Cutting and Staining (Krajian) has been extensively revised. Dr. Krajian, unfortunately, died in May, 1962, during the time the sixth edition was in press.

The section is profusely illustrated with original Krajian photomicrographs, some in black and white and some in color. New material includes otohistologic technic—advances in otohistologic selective stains and chemical coloration methods by the use of radioactive metallic salts and other rare metallic salts and chemicals; a new selective hematoxylin stain demonstrating smooth and striated muscle fibers, elastic and connective tissue, bone tissue, nerve fibers, plasma cells, erythrocytes, and leukocytes; a new differential nerve stain demonstrating fibrin, smooth and striated muscle fibers, elastic and connective tissue, bone tissue, hair cells, erythrocytes, and leukocytes; chemical coloration of temporal bone sections for the identification of bone tissue, smooth and striated muscle fibers, connective tissue, and nerve fibers; a new chemical coloration method for the demonstration of nerve fibers, smooth and striated muscle fibers, connective tissue, bone tissue, blood vessels, bone marrow, and other elements; a myelin sheath stain applicable to frozen sections from central nervous system, both human and animal; and a new decalcification method on temporal bones, employing a controlled shaking machine and modified decalcifying fluid.

This section could almost be considered a textbook in itself, so complete is it in its discussions of histologic methods.

Electrocardiography (Elson) includes not only an excellent discussion of the fundamentals but also information that is necessary for interpretation. The normal electrocardiogram and the more common abnormalities are discussed in detail.

Once again the index has been expertly prepared by Mrs. Addine Erskine, and the extensive use of cross references will enable the reader to locate any desired material rapidly and without frustration. It is only through the serious effort and the excellent cooperation of all the contributors that the preparation of this text was possible. We wish to express to them our sincere thanks and indebtedness.

HEMATOLOGY

Hematology is an important department of the laboratory. For many years hematologists have been concerned with various hematologic procedures: first, with an examination of unstained blood and later with the use of specific tinctorial methods for the demonstration of various kinds of white cells. Then methods of absolute blood counting were introduced, together with special tests, such as blood sedimentation, cell volume, bleeding time, clotting time, blood typing, oxydase reaction, supravital staining, and a method of differential counting introduced by Victor Schilling.

Although technical advances have been made in blood examinations and many new clinical observations have been recorded regarding the various blood dyscrasias, much of our information in the past has come from anatomic investigations.

Recently, however, more important advances have been made since the physiologists and experimental physiologists have together applied themselves to the unknown problems of blood development and its various aberrations. Within the past 15 yr. immunohematology has become a branch in itself. The investigators in this field have added much to our knowledge of blood dyscrasias. The use of anticoagulants in the treatment of thromboembolic disease has stimulated a renewal of interest in the mechanism of blood coagulation. Pauling's work in hemoglobin has opened an entirely new field in molecular disease of hemoglobin. These are but a few examples of the dynamic approach to problems in the field of hematology.

In connection with the contents of this section, one must bear in mind that hematology is not a single science but rather a part of clinical medicine. A good hematologist must first and foremost be a skilled clinician capable of using all the diagnostic methods known to medicine necessary to arrive at the correct hematologic diagnosis. This point has been emphasized by Riser[1] in an article entitled, *The practical handling of hematology by the clinical pathologist.* He decided very properly that the clinical pathologist in order to be a good hematologist must not only know the individual blood cells but also be skilled in the interpretation and correlation of the clinical laboratory values in the light of the clinical history and physical findings. Riser stated that the clinical pathologist is often regarded as a highly specialized magician imbued with the power of visualizing the complete blood picture upon study of a single blood spread, without previously having any knowledge of the clinical history or physical findings of the patient. The diagnosis can be arrived at only after indicated laboratory studies are completed and careful integration and correlation of all available information have been carried out. Sometimes it is necessary to study the patient over a period of time before the correct diagnosis is evident. The practice of sending blood films to the clinical pathologist with request for hematologic diagnosis is to be decried. It is often necessary for us to write for all the pertinent data before venturing on any conclusions. It is erroneous to use bone marrow studies alone and quite separate from all the other facts of the case as a means of diagnosis. Emphasis is therefore to be laid on the fact that (1) a complete study of the blood must be made from a laboratory standpoint and (2) these data must be correlated very carefully by either the clinician or the clinical hematologist in order to arrive at a probable diagnosis. Without minimizing in any way the importance of the following pages devoted to hematology from a laboratory standpoint, one must bear in mind that a technician cannot possibly be a hematologist and that a clinical pathologist cannot be a hematologist unless he is an accomplished clinician.

Chapter 59

General considerations

JOHN D. BAUER

ORIGIN OF BLOOD CELLS

There still is considerable discussion as to the origin and development of the various blood cells. Certain points are still in controversy as to the monophyletic or polyphyletic development of the principal leukocytes. For an extensive review and bibliography of this subject, we recommend Downey's *Handbook of hematology.*[2] In this handbook the various theories of the origin of blood cells have been exceedingly well portrayed in the section by William Bloom.

Blood formation in embryo and fetus

It is generally agreed that the most primitive blood formation in the early embryo begins with the layer known as **embryonal mesenchyme.** The first cells to be formed in this early period of blood formation are red cells often referred to as **primitive erythroblasts.** In this very early stage or mesoblastic period it is very difficult to find cells that correspond to the white cells of the adult. It is also important to remember that at this stage blood formation takes place within **blood islands** in the yolk sac of the embryo. These early cells are large and have large hyperchromatic nuclei.

At about the second month of fetal development, there begin to appear cells that correspond to the white blood cells in the adult, and, in addition, megakaryocytes can be demonstrated in the liver. At this stage the liver becomes a blood-forming organ and presents red blood cell formation as well as white blood cell formation. These cells originate from the sinusoidal reticulum cells. Associated with this activity of the liver is a modest activity of the spleen, which at first is most concerned with erythropoiesis but later is concerned with the formation of lymphocytes. At about the fifth month of fetal development, the final phase of hematopoiesis is instituted in the fetus. At this point the bone marrow begins to inaugurate its ultimate growth as one of the greatest blood-forming tissues in the human body. Simultaneous with this development of the bone marrow, the lymphatic system and lymph nodes begin the development of lymphocytes (Fig. 333).

In the fetus, the early red cell development or **primitive** development shows cells somewhat similar to the abnormal red cells seen in pernicious anemia. An interesting point about this similarity is that this primitive erythropoiesis gives way to definitive erythropoiesis (the adult type of normal erythropoiesis) at the same time that the fetal liver begins to develop. It is rather interesting that with the administration of liver therapy to patients with pernicious anemia (primitive erythropoiesis), the erythropoiesis reverts to the definitive type.

Blood plasma. Blood plasma can be detected at about the fourth month of intrauterine life. Embryonal plasma contains a higher percentage of globulin than of albumin. Although the mesenchymal origin of the formed blood elements is generally accepted, the origin of the plasma is not well established. Shields[3] recently summarized the existing evidence for the origin of plasma. Cells of mesenchymal origin, by releasing portions of their protoplasm (hyaline bodies) and by disintegrating, produce a sol called the blood plasma. Thus the mesenchyme gives rise to both cellular and lipid elements of the blood.

Leukocytes. Regarding the development of leukocytes, there is still considerable disagreement concerning each type of white blood cell, and as a result, there have appeared several schools of theory concerning the development of leukocytes. Fig. 330 is a chart representation of the various theories of blood formation. These theories, briefly, are divided into 2 major groups, the **monophyletic** and the **polyphyletic** schools.

The monophyletic theory insists that all blood cells, regardless of their character, are derived from a single primitive blood cell that perhaps corresponds to the primitive mesenchyme of the embryo. In the normal adult human being it is difficult, first of all, to find cells that are identical with primitive mesenchymal cells, and it is even more difficult to identify steplike development of such primitive cells through the various forms of leukocytes and erythrocytes. Another strong position that the monophyletists take is that in the adult there are cells that are totipotential, that is, they have the power of developing in any direction. Although this is the complete monophyletic theory, there are other men (Downey, Pappenheim, and Ferrata) who believe in the monophyletic theory but who do not agree that certain cells are totipotential. These men have been labeled "neounitarians" because they believe that, once certain cells have become functionally differentiated, they cannot revert to other cell types.

The polyphyleticists can also be divided into several subgroups, such as **dualists** (2 series of development of white blood cells), **trialists** (3 main stems of development), etc. Ehrlich and Naegeli represent proponents of the dualistic school and Schilling and others, the trialistic.

Suffice it to say at this point that the almost religious fervor in the crusades for various theories of blood formation is now much more a matter of the historic past than of interest to hematologists.

The various theories as to the origin of blood cells have been exceedingly well portrayed in a monograph by Bloom.[4] We are indebted to the author of this monograph and to the publisher for permission to quote from this splendid review of this subject and to quote it freely. Bloom states that the so-called trialism theory of Schilling is about as follows: There proceeds from the mesenchyme cells myeloblastic, lymphoblastic, and histiocytic cells, the last of which become monocytes.

Of Cunningham, Sabin, and Doan's theory, Bloom states: "They derive lymphocytes, granular leukocytes, and monocytes from fixed reticular cells by way of a small round precursor which they call a primitive blood cell.

Fig. 330. This chart summarizes the principal points in conflict and in agreement between the various theories advanced to explain the histogenesis of the blood cells. There are 3 levels of maturation common to all; in the first level, primitive undifferentiated mesenchymal cells provide the blast cells of the second level, which in turn, by maturation and division, become the completely differentiated cells of the circulating blood, represented by the third level. The degree of polygenesis is determined by the number of partially differentiated (blast) cells believed to be necessary in order to render accordant the experimental facts and observations as interpreted by the various investigators who comprise the schools of thought shown in the lower portion of the chart. The principal difference, as indicated, is in the degree of prepotency ascribed to the blast cells, the unitarians feeling that a single common ancestor (the lymphocyte) may differentiate into any of the mature types of cells. Attributing lesser degrees of potentialities to this cell results in increasing degrees of polyphyletism, which in the extreme construction requires a separate blast cell for each of the circulating elements, and a separation of the reticuloendothelial system of cells into its component units, each with different potentialities.

Fig. 331. This chart condenses, by diagram, the monophyletic interpretation of the literature that is concerned with the relationships between the cells of the blood and those of the tissues. A common undifferentiated totipotential cell is postulated and identified with the hemocytoblast of Ferrata, the lymphoidocyte of Pappenheim, and the blood lymphocyte, lymphoblast, myeloblast, megaloblast, and monoblast of the polyphyletic adherents. In theory the small lymphocyte of the blood is believed simply to be a temporary resting phase of the larger lymphoid cell and may differentiate into the other cells, as shown, either directly or after reverting back to the large tissue cell of the Ferrata type. The small or large lymphocyte may also develop into the more mature blood cells directly without going through the maturation phases of these cells, and, finally, after having so differentiated, it may dedifferentiate back to the primitive totipotential level. The reticulum and endothelial cells of the reticuloendothelial system are believed to be potentially identical, differing only in shape. They give rise to the lymphocytes of the blood, either directly or through a primitive tissue cell similar to the hemohistioblast of Ferrata. Opinion varies between different supporters of the monophyletic school as to the importance of the transition from monocyte and clasmatocyte back to lymphocyte, as well as other minor points intentionally omitted on this chart, in order to emphasize the important concepts involved in this theory of blood formation.

The formation of granulocytes takes place in the bone marrow, that of monocytes in the spleen, and of lymphocytes in spleen and lymph nodes. These authors also describe the development of the red blood cells and macrophages (clasmatocytes) from endothelium."*

The dualistic theories of Ehrlich, Schridde, and Naegeli derive the blood cells from 2 sources, myelocytic and lymphocytic.

The extreme unitarians, according to Bloom, are Dominici, A. Wolff, Ciaccio, Maximow, Dantschakoff, Weidenreich, Latta, Jordan, Jolly, Jordan and Spiedel, Bloom, Kingsbury, and Maximow and Bloom. They believe that the 3 stem cells of the connective, lymphatic, and myeloid tissues of the adult and of the various sites of blood formation in the embryo are representatives of a single cell type. Maximow adopted the term **hemocytoblast** for the free stem cell.

There are so-called neounitarian theories, of which Pappenheim, Ferrata, and Downey are the leading exponents. They uphold the unitarian theory of blood cell formation and admit to a greater or lesser degree the morphologic identity of the free stem cells in the myeloid and lymphatic tissues. They believe that the cells in their respective situations are functionally differentiated.

It may be well to summarize in tabulated form the various and differing conceptions of the origin of the white blood cells. Wiseman[5] (Fig. 330) summarizes the principal points that are in conflict and in agreement between the various theories that have been advanced to explain the histogenesis of the blood cells. In another chart (Fig. 331) Wiseman shows the monophyletic interpretation of the literature that is concerned with the relationships between the cells of the blood and those of the tissues.

A recapitulation of the preceding shows blood cells, according to the unitarian group, coming from undifferentiated mesenchymal cells; according to the dualists, the sources are myelocytic and lymphocytic, and some origin from the histiocytes of the tissues. The trialism school, which is headed by Schilling

and his followers, believes in three points of development of white cells. Fig. 332 illustrates the Schilling trialism theory.

Whatever the theories, the biologic fact remains that the first white cells appear at about 2 mo. They are myeloblasts. At 3 mo., granulocytes (mainly eosinophils), lymphocytes, and megakaryocytes can be detected in the fetal blood. In the fifth month, monocytes make their appearance. There is good evidence that all of these cells are produced by the reticuloendothelial system.

NOMENCLATURE OF HEMATOLOGY

There is considerable confusion in hematologic literature due to terminology. Osgood suggested a nomenclature for the erythrocyte and granulocyte series because of the disagreement in definitions and the inappropriateness of the terms in current use. He called attention, for instance, to the term **normoblast,** which is a combination of a Latin and a Greek root which should mean a normal stem cell since the termination blast is ordinarily employed only for the most immature cells of a series. The cell, however, is neither a stem cell nor a normal cell of the blood. He further maintains very properly that the derivation for the erythrocyte series is from the Greek word meaning **nucleated.** The old term **myeloid series,** meaning marrow-like cells, is a misnomer because these are cells forming an integral part of the marrow. This does not differentiate them from cells of the monocyte, plasmacyte, or erythrocyte series which are also found normally in the marrow. Osgood believes, as we do, that the term **granulocyte series** is more logical for all cells of this group.

Because of the confusing terminology that has developed in the field of hematology, a special committee of outstanding hematologists from various parts of the United States met in Chicago in October, 1947, for the purpose of attempting to clarify the nomenclature of cells and diseases of the blood and blood-forming organs. The major recommendations are listed in Tables 221-223. "**It is not the intention of the Committee to imply from its recommendation of terms to be used that the origin of all these cells has been settled.**"

It should be mentioned here that not all of the members of the Committee were in entire accord as to the final nomenclature to be used, but they felt that some modicum of agreement would help eliminate some of the confusion in the field of hematology. Despite the efforts of this group to unify the nomenclature, there are certain terms of historic use that will be difficult to eliminate from the writing and speaking of hematologists the world over.

Weicker,[6] on the basis of his own and others' investigations, suggested a karyometric method of classification of cells based on mathematical nuclear volume studies and on the fact that, after nuclear division, the volumes of the daughter nuclei are always in a

Table 221. *Recommended terms and terms to be avoided when referring to specific cells of the erythrocytic series**

Term to be used	*Terms to be avoided*
Rubriblast	Erythroblast, megaloblast, pronormoblast, promegaloblast, normoblast, hemocytoblast, stem cell, myeloblast, lymphoidocyte, karyoblast
Prorubricyte	Erythroblast, megaloblast, pronormoblast, normoblast, macronormoblast, macroblast, prokaryocyte
Rubricyte	Normoblast, pronormoblast, macronormoblast, erythroblast, polychromatophilic normoblast, karyocyte
Metarubricyte	Normoblast, erythroblast, metakaryocyte
Reticulocyte†	
Erythrocyte	Red blood cell, erythroplastid, normocyte, akaryocyte

Table 223. *Recommended terms and terms to be avoided when referring to specific cells of the blood and blood-forming organs**

Name of series	*Term to be used*	*Terms to be avoided*
Lymphocytic	Lymphoblast	Myeloblast, hemocytoblast, lymphoidocyte, stem cell, lymphocyte
	Prolymphocyte	Large lymphocyte, pathologic large lymphocyte, atypical leukocytoid lymphocyte, monocyte, immature lymphocyte
	Lymphocyte	Small, medium or large lymphocyte, normal lymphocyte, small, medium or large mononuclear
Monocytic	Monoblast	Myeloblast, hemocytoblast, lymphoidocyte, lymphocyte, stem cell, immature monocyte
	Promonocyte	Premonocyte, hemohistioblast, immature monocyte, Ferrata cell
	Monocyte	Large mononuclear, transitional, clasmatocyte, endothelial leukocyte, histiocyte, resting wandering cell
Granulocytic	Myeloblast	Granuloblast, hemocytoblast, lymphoidocyte, lymphocyte, stem cell
	Progranulocyte	Promyelocyte II, leukoblast, myeloblast, premyelocyte, promyelocyte, progranulocyte A
	Myelocyte	Granulocyte, myelocyte B, nonfilament, class I
	Metamyelocyte	Metagranulocyte, juvenile, myelocyte C, nonfilament, class I
	Band cell	Staff cell, stab cell, nonfilament, class I, rod nuclear, polymorphonuclear, stabkernige, rhabdocyte, nonsegmented
	Segmented	Polymorphonuclear, filamented, class II, III, IV, or V, lobocyte
Plasmacytic	Plasmablast	Myeloblast, hemocytoblast, lymphoidocyte, lymphocyte, stem cell, lymphoblastic plasma cell, myeloma cell
	Proplasmacyte	Türck cell, Türck irritation form, lymphoblastic or myeloblastic plasma cell, myeloma cell
	Plasmacyte	Plasma cell, Unna plasma cell, Marschalko plasma cell, plasmacytoid lymphocyte, myeloma cell
Thrombocytic	Megakaryoblast	Megalokaryoblast
	Promegakaryocyte	Premegalokaryocyte
	Megakaryocyte	Megalokaryocyte
	Thrombocyte	Platelet, thromboplastid
	Disintegrated cell	Senile cell, smudge, basket cell, smear cell, degenerated cell

*From Committee for Clarification of the Nomenclature of Cells and Diseases of the Blood and Blood-Forming Organs, Am. J. Clin. Path. **18**:443-450, 1948.

constant proportion to each other and to the mother nucleus.

In the erythroid series, this classification would be as follows:

If the letter K represents the nuclear volume:

K_2 represents an early erythroblast with nuclear diameter of 13μ

K_1 represents a late erythroblast with a nuclear diameter of 10.3μ

$K_{1/2}$ is assigned to a basophilic normoblast with a nuclear diameter of 8.2μ

$K_{1/4}$ corresponds to a polychromatic normoblast with nuclear diameter of 6.5μ

$K_{1/8}$ signifies an oxyphilic normoblast with a nuclear diameter of 5.2μ

In the granulocytic series, the classification would be as follows:

K_1 is myeloblast with nuclear diameter of 15μ

K_2 is promyelocyte

$K_{1\text{-}1/2}$ is myelocyte

$K_{1/2\text{-}1/3}$ is granulocyte

Glossary of common hematologic terms

hematopoietic organs The blood-forming organs.

erythropoiesis The manufacture of red blood cells.

erythrocytes Red blood corpuscles.

normocytosis A condition characterized by the presence of normal-sized erythrocytes *(normocytes).*

microcytosis A condition characterized by the presence of small erythrocytes *(microcytes).*

macrocytosis A condition characterized by the presence of large erythrocytes *(macrocytes).*

anisocytosis Abnormal variation in the size of erythrocytes.

poikilocytosis The appearance of abnormally shaped erythrocytes: pear-shaped, oak-leaf, club, or crenated.

crenation The scalloped or notched appearance of the edges of erythrocytes found in pathologic conditions, or caused by undue pressure when making a blood film; also noted when erythrocytes are suspended in hypertonic solutions.

normochromia or *normochromasia* Normal pigment content of erythrocytes.

hypochromia or *hypochromasia* Decreased pigment content of erythrocytes.

hyperchromia or *hyperchromasia* Increased pigment content of erythrocytes.

polychromasia The presence in the fixed blood film of blue-gray-staining erythrocytes.

basophilic punctation or *basophilic stippling* A characteristic of mature erythrocytes which, under certain toxic conditions, show dark staining of punctate bodies in the cytoplasm, demonstrable by routine staining methods.

reticulocyte A slightly immature red cell containing a dark-staining weblike or lacelike structure, which can be demonstrated only by some type of supravital staining.

basophilia of the erythrocytes The appearance in the circulating blood of immature erythrocytes which show bluish gray staining of the cytoplasm demonstrable by routine staining technics.

normoblast A nucleated red blood cell.

megaloblast An abnormal primitive nucleated red blood cell.

hemacytometers Instruments used in counting blood cells.

anemia A symptom complex accompanied by reduction in red blood cells, hemoglobin, and red cell volume per cent of variable degree.

oligocytosis, or *hypoglobulia,* or *erythropenia,* or *oligocythemia* A low red blood cell count.

erythrocytosis, or *polycythemia,* or *hyperglobulia* An elevated red blood cell count.

rouleaux formation of erythrocytes The tendency of erythrocytes to lie with overlapping edges or in roll formation, such as may be seen when a stack of coins is pushed over.

hemoglobin An iron-bearing protein which gives the red color to blood.

hemoglobinometers Instruments used for measuring hemoglobin.

oxyhemoglobin The bright red hemoglobin that is loosely combined with oxygen and present in the arteries.

reduced hemoglobin A combination of hemoglobin and carbon dioxide and present in venous blood.

leukopoiesis The manufacture of white blood cells.

leukocytes White blood cells.

leukocytosis A high white blood cell count.

neutrophilia A high neutrophil count.

lymphocytosis A high lymphocyte count.

monocytosis A high monocyte count.

eosinophilia A high eosinophil count.

hyperleukocytosis Leukocytosis over 25,000.

leukopenia A low white blood cell count.

neutropenia A low neutrophil count.

lymphocytopenia or *lymphopenia* A low lymphocyte count.

monocytopenia or *monopenia* A low monocyte count.

hypoeosinophilia or *eosinopenia* A low eosinophil count.

toxic granules Large irregularly clumped granules seen in the cytoplasm of neutrophils in disease processes such as severe bacterial invasion and chemical intoxication.

hemogram A complete picture of the blood, including numerical and differential counts, hemoglobin estimations, blood platelet counts, reticulocyte counts, special tests, and complete examination of stained erythrocytes.

hemogram of Schilling A linear depiction of the differential count of leukocytes so arranged as to show at a glance a pathologic shift in the differential picture.

nuclear shift An increase or decrease in the number of neutrophilic cells of one type over another.

degenerative leukocytic blood picture One which shows an increase in the number of stab cells over normal (together with other findings) due to a toxic depressing influence on the hematopoietic organs.

regenerative leukocytic blood picture One which shows an increase in the number of juvenile or metamyelocyte cells over normal or an occasional myelocyte, usually with an increased white blood cell count due to stimulation of leukopoiesis.

leukemoid or *liberation* or *flooding leukocytic blood picture* One which shows a marked increase in the number of myelocytes, juvenile, and stab cells over normal cells signifying total loss of defense of the hematopoietic organs; nucleated red blood cells may be seen; must be differentiated from leukemia.

leukemia A fatal disease of unknown origin which primarily involves white blood cells which may or may not be increased in numbers in the blood stream; pathologic forms of leukocytes, often very young, are always present in this disease.

blood platelets (thrombocytes) Small bodies found in the circulating blood which bear an important relationship to blood clotting.

thrombocytosis A high blood platelet count.

thrombopenia or *thrombocytopenia* A low blood platelet count.

hyperplasia An overgrowth of tissue; in reference to blood formation may refer to any or all of the blood elements; most strikingly seen in the leukemias.

hypoplasia Diminished tissue formation.

aplasia Cessation of tissue formation.

blood dust or *hemokoniae* Small refractive bodies in the blood.

chemotaxis Phenomenon shown by certain living cells of moving toward (positive) or away from (negative) certain other cells or substances which exert a chemical influence.

agglomeration Adhering together of cells of the same kind, such as rouleaux formation of erythrocytes, groups of white cells, thrombus formations of blood platelets, heaping of eosinophils, etc.; important in sedimentation tests and in the making of blood spreads.

mitosis Indirect cell division through nuclear change or *karyokinesis;* the typical mode of vision of active somatic cells and germ cells.

HEMATOPOIETIC ORGANS AND THEIR PHYSIOLOGY

Embryonal blood development

Blood cell formation takes place primarily within the body in the embryonal state in the area vasculosa. From this emanate angioblasts. The nomenclature in this stage of embryonal blood development is still in controversy. Minot terms the first intravasal cells **mesamoeboid** cells and believes them to be the parent cells of all blood cells (Pappenheim, Maximow, Dantschakoff, Naegeli, Schridde). These cells are transformed into erythroblasts by the formation of hemoglobin; in the human embryo, this occurs at the 8 mm. stage of development. Sabin noted a very early genetic separation of granulocytic, monocytic, and lymphocytic centers. She believed that granulocytes came into existence from the direct transformation of angioblasts, and that lymphocytes originated from body

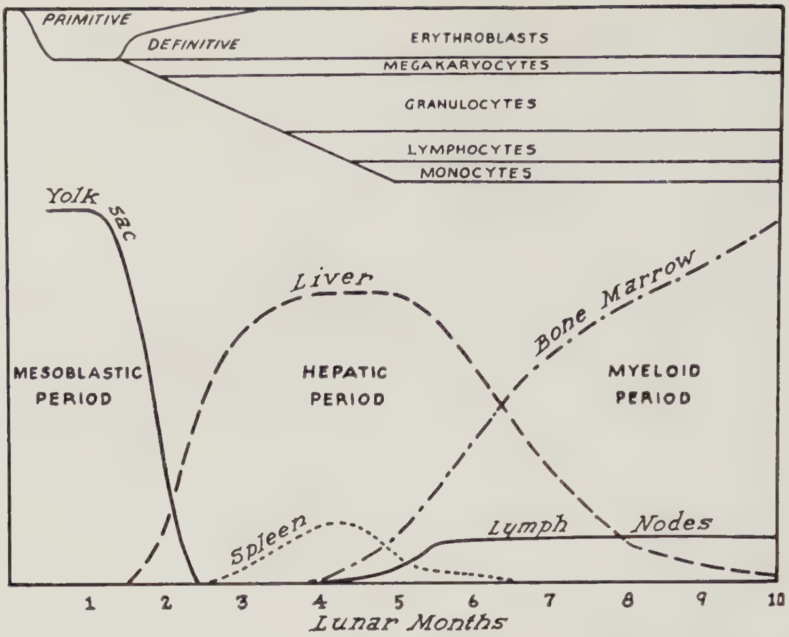

Fig. 333. Stages of hemopoiesis in embryo and fetus, indicating comparative participation of chief centers of hemopoiesis and approximate times at which different types of cells make their appearance. (From Wintrobe, M. M.: Clinical hematology, Philadelphia, 1952, Lea & Febiger.)

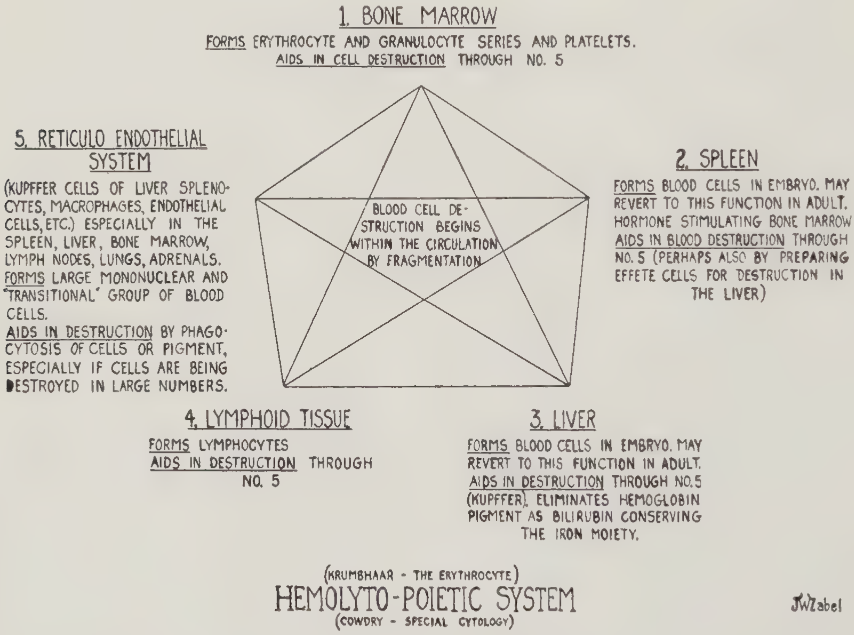

1. BONE MARROW

Fig. 334. Blood cell formation and destruction according to Maximow.

cells at a considerably later period than the other cells just described.

The first localization of hematopoiesis may be observed in the liver of the 12 mm. embryo, which is in the third month of embryonal life. At this time there begins the development of the outstanding blood organ, namely, the bone marow. While it is true that the differentiation of cells occurs in early embryonal stages, physiologic regeneration of injured or lost blood cells later in life suggests the possibility of later new differentiation of various cell types from certain elements that remain indifferent and latent, that is, mesenchymatous or angioblastic cells. Blood cells develop outside the sinusoids from mesenchymal cells (extravascularly), as well as within the sinusoids from endothelial cells (intravascularly).

Bone marrow formation begins in the third embryonal month and soon changes into myelocytic elements. Transformation of connective tissue cells into lymphoid wandering cells soon ceases, and differentiated tissue—erythroblasts, myeloblasts, and giant cells—appears. Erythroblastic and megaloblastic cells soon are seen. Granulocytic elements are scarce at first and are isolated or in small groups. The differentiation of basophilic and eosinophilic cells in the bone marrow is a very early phenomenon. Embryonal bone marrow is very rich in cells and remains so in the first years of life, gradually changing as infancy begins. It is to be noted that the bone marrow of the long bones in embryos and children is more hematopoietic than that of adults. Attention will later be called to the fact that bone marrow may be changed into fat and may change back again into red marrow. Red marrow is found in all bones of newborn infants, decreasing in the child up to the end of the seventh year. Gradual concentration of the marrow into the smaller bones occurs, and red marrow is seen in adult life in the proximal epiphyses of the long hollow bones, the skull bones, the ribs, the sternum, the scapulae, the clavicles, the vertebrae, and the flat pelvic bones.

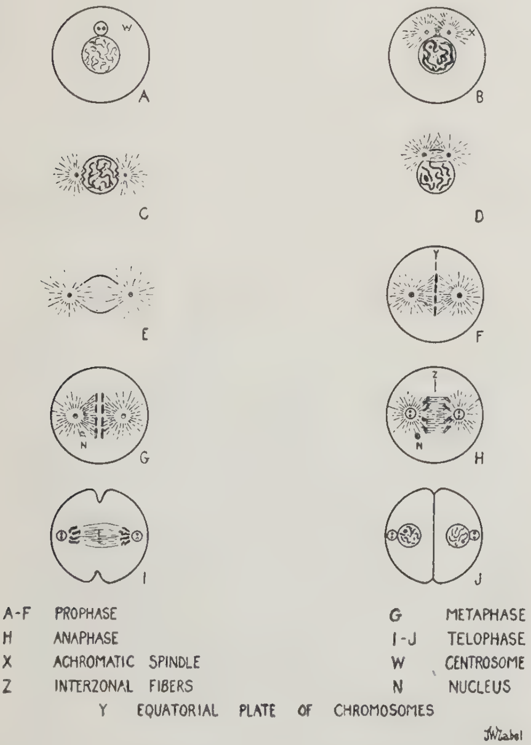

Fig. 335. Successive stages of mitosis. (After Wilson.)

In the human being after birth, hematopoiesis is concentrated in the bone marrow and the lymph nodes. Normal bone marrow is the primary source of erythrocytes, cells of the myelocytic series, and platelets. Lymph nodes are the major source of lymphocytes, with the spleen contributing to the production of these cells.

General facts on cellular development

All cells arise from pre-existing cells by division. This fact was first brought out in the celebrated dictum of Rudolf Virchow: "*omnis cellula e cellula.*" Cells divide in 2 ways—by amitosis and by mitosis. Amitosis is direct division of cells by the simple fission of nucleus and cytoplasm. It is not preceded by structural metamorphosis of the nucleus or cytoplasm. In mitosis complicated changes take place in the nucleus. Since these changes give rise to threadlike structures developed out of the nuclear chromatin, the process is termed mitosis from the word **thread,** in contrast to amitosis or **no thread.** The distinctive feature of mitosis is the production of a characteristic number of chromosome bodies, their accurate lengthwise halving, and the equal distribution of these halves to the daughter cells.

Mitosis or **karyokinesis** was first discovered by Schleicher and was studied first by Flemming. It is the most important method of cell division. There are different types of indirect generation. The phases of the process, beginning with the state of rest, are classified as progressive and regressive. The progressive changes of structure occur between rest and the phase of metakinesis or mother star. The regressive retrocede from the height of metakinesis to the resting stage of the daughter cells. The order and nomenclature of the phases are as follows.

First, the **progressive phases** occur. These are divided into the **prophase** and the **metaphase.** In the prophase stage there are (1) the phase of rest, (2) the phase of gross segmentation, and (3) the phase of the ovum. In the metaphase stage there are the phase of transverse segmentation and the phase of the mother star or metakinesis. In the **prophase** the centrioles separate from each other with the formation of attraction spheres around each of them while the chromatic masses change into **chromosomes,** the number of which is constant in a given species. In man, there are 46 chromosomes (22 pairs of autosomes, nonsex chromosomes, and 2 sex chromosomes, XX in the female and XY in the male). In the **metaphase** each chromosome splits into 2 equal parts.

There are 2 states in the regressive phases, the **anaphase** and the **telophase.** In the **anaphase** the halves of a particular chromosome separate and each half approaches 1 of the 2 centrioles which have migrated in the meantime to opposite poles of the cell. In the **telophase** the formation of the 2 daughter nuclei and the division of the cytoplasm into masses surrounding each daughter nucleus takes place.

In the **prophase** state, the chromatic net of the nucleus becomes richer, and the nucleus increases in size. The idiozome and the centrioles become visible. Reticulation occurs preparatory to the organization of the ovum.

In the **phase of the ovum,** there are seen 2 classes of trabeculae, primary or gross, formed principally from the chromatin, and secondary or fine, constituted by the linin threads. The primary filaments or chromosomes are disposed in hairpinlike forms oriented almost always in the same direction, with the elbows turned to one side. The site of the nucleus at which the angles of the hairpins converge presents a space devoid of filaments, the polar field. The opposite extreme, the antipode or contrapolar field, is filled by the accumulation and intercrossing of the free ends of the chromosomes.

At the end of the **spireme stage** the chromatic filament divides into the number of chromosomes characteristic of the species of the cell. These chromosomes assume the form of hairpins.

During the **metaphase** or in metakinesis the chromatic threads or hairpins are arranged in the form of a star. Another characteristic of this phase is the enlargement and dislocation of the achromatic spindle by the division of the chromosomes. The chromosomes dispose themselves around the widest region of the spindle in the form of a star at the perpendicular or equatorial plane of which occurs the segmentation of the nucleus and protoplasm.

In the **anaphase** the chromosome hairpins are duplicated and begin to separate from the elbows toward the extremities. There is now seen a running of the achromatic handles toward the poles forming a double star or diaster.

In the **telophase** the centrosomes and the spindle disappear while a fine membrane forms around the daughter chromosomes. The nucleus takes the form of a horseshoe. This protoplasmic furrow reaches the equator of the spindle and forms a thin bundle of very fine threads. Shortly after this, the bundle bursts and the intermediary body disappears.

In direct or **amitotic** division the nucleus is thought to constrict and finally to divide into 2 halves, a nucleolus going to each daughter nucleus. There is much discussion as to whether this process actually occurs under normal conditions.

The physiologic basis of nuclear division is the 2-fold increase of nuclear deoxyribonucleic acid. Various methods of division have been described. If the daugther cells are replicas of the mother cell, we speak of **homoplastic division.** If the daughter cells differ from the mother cell, we speak of **heteroplastic division.** Many subdivisions are possible; e.g., one daughter cell may develop to become a cell similar to the mother cell, whereas the other daughter cell may become a different type of cell; both daughter cells may develop into cells which differ from the maternal cells; while, last, the daughter cells may differ not only from the mother cell, but also from each other.

A knowledge of cell division and chromosomes has gained increased importance with the advent of phase microscopy, electron microscopy, and clinical methods of chromosome counting. The first 2 methods allow one to visualize chromosome activity and composition and to investigate the action of cytotoxic drugs, whereas the latter method allows genetic evaluation of disease processes.

Pathology of cell division

Many of the cytotoxic drugs used in the fight against cancer (and therefore against leukemia) attack cells in mitosis or attack the chromosomes. Colchicine and cortisone damage the cell in mitosis, whereas the folic acid antagonist aminopterin injures the chromosomes.

In hematology, microblasts and abnormal giant cells represent instances of abnormal cell division, whereas megaloblastic anemias, aplastic anemias, aplastic crises of hemolytic anemias, and agranulocytosis represent instances of arrest of cell division at various levels.

HUMAN CHROMOSOMES[7-14]

Chromosomes can be divided into the **diploid autosomal chromosomes,** which have no relation to sex, and the **haploid sex chromosomes,** which, as the name implies, determine the sex of the individual.

The chromosomes consist of deoxyribonucleic acid nucleoprotein which carries the genes, the hereditary units. With the exception of the germ cells, all somatic cell nuclei of a given species contain a constant amount of deoxyribonucleic acid. All chromosomes are diploid with the exception of the chromosomes of the mature germ cell, which are haploid. The mitotic division as described applies to all chromosomes of the female organism and to 22 pairs of the 23 pairs of the male chromosomes.

Sex chromosomes

In man there is present an X chromosome and a Y chromosome. The Y chromosome is responsible for the masculine sex characteristics. The mature male germ cell contains 22 single autosomes and either an X chromosome or a Y chromosome. If a female germ cell, which carries a single X sex chromosome, receives a Y chromosome from the male germ cell, the offspring will be of the male sex. If the female germ cell receives an X chromosome, the child will be female.

The female cell is characterized by a pair of like XX chromosomes, whereas the male cell has a pair of unlike chromosomes XY. The recognition of the sex chromatin in the cell allows the investigation of cases in which the chromosomal sex is suspected to differ from the anatomic sex.

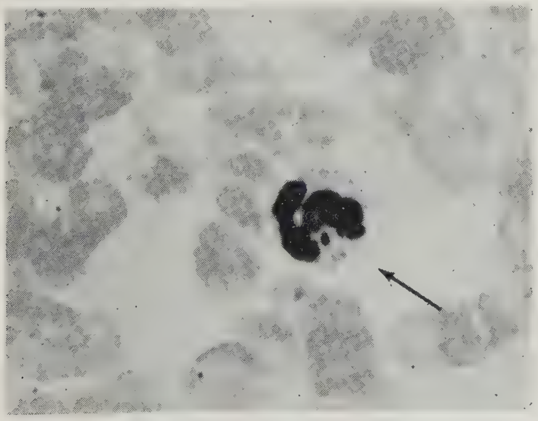

Fig. 336. Drumstick in polymorphonuclear leukocyte of female. (From Bauer, J. D., Toro, G., and Ackermann, P. G.: Bray's clinical laboratory methods, St. Louis, 1962, The C. V. Mosby Co.)

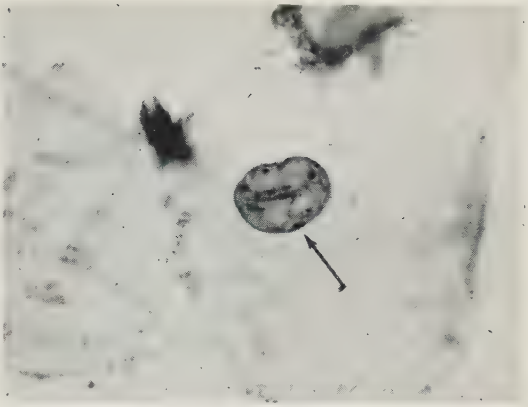

Fig. 337. Buccal epithelium revealing sex chromatin body. (From Bauer, J. D., Toro, G., and Ackermann, P. G.: Bray's clinical laboratory methods, St. Louis, 1962, The C. V. Mosby Co.)

In the individual cell, the **Barr body** or sex chromatin body probably represents the second X chromosome and is therefore not seen in the cells of the male but is detected only in the cells of the female. In the epithelial cell it appears as a mass of biconvex chromatin measuring about 0.7-1.2μ in diameter, situated within the nucleus so closely applied to the inside of the nuclear membrane that it cannot be separated from it even under oil immersion.

Methods of nuclear sexing

Several methods of nuclear sexing can be employed: (1) skin biopsy, (2) buccal smear, and (3) peripheral blood film.

Skin biopsy and buccal smear methods are outside the field of hematology but references are given because the peripheral blood film method should always be complemented by one or the other additional method.

Peripheral blood film technic

In at least 6 out of every 500 neutrophilic polymorphonuclear leukocytes in the female there is a small drumsticklike projection attached to the nucleus. This projection, made of nuclear chromatin, has a small, slightly ovoid head measuring 1.5μ in diameter and is attached to the nucleus by means of a delicate threadlike structure. It can also be seen in the eosinophils and basophils. If strict criteria are employed, the frequency of drumsticks in polymorphonuclear cells and of sex chromatin in buccal cells is comparable. Strict criteria are necessary since in the male polymorphonuclear cell variously sized and shaped nuclear projections can be seen. Some resemble drumsticks; others are triangular and pointed. It is conceivable that the drumstick represents a genetically determined sex characteristic rather than the actual sex chromosome. The technic employs a regular thin blood film stained with Wright or Giemsa stain.

Sex chromosomal defects include gonadal dysgenesis (Turner's syndrome and Klinefelter's syndrome), true hermaphroditism, and superfemale.

Turner's syndrome is due to ovarian dysgenesis. Anatomically these patients are females, but the cellular chromosome pattern is negative (XO). At puberty, they fail to develop female sexual characteristics and often show webbing of the neck. The ovaries consist mainly of stroma.

Klinefelter's syndrome is due to testicular dysgenesis, and though the anatomic build is male, the nuclear chromatin pattern is female (XXY). At puberty, these boys fail to develop. The testes consist mainly of hyalinized connective tissue and Sertoli cells.

Both syndromes are causes of sterility.

In true hermaphroditism, the gonad is an ovotestis; therefore the chromosomal sex may be either XX, XY, or mosaic (both).

The superfemale pattern XXX is probably due to nondysjunction of the sex chromosome during the formation of the parental cells. Nondysjunction can also explain Klinefelter's and Turner's syndromes as well as some lethal combination such as YO and XYY.

Autosomal chromosomes

Recently introduced methods of cell culture which allow the analysis of human chromosomes at metaphase have shed new light on many diseases and have opened an entirely new field of investigation. These investigations touch upon hematologic problems since abnormal karyotypes have been described in such conditions as hemophilia, leukemia, and Gaucher's disease and following irradiation. The chromosomes can be visualized only during nuclear division in metaphase. Each chromosome is characterized by its over-all length, by the length of its arms, and by the position of the centromere. Each chromosome has an identical mate in the nucleus irrespective of how they are arranged. They can be photographed, cut out, arranged in identical pairs, and numbered according to the Denver system (human karyotype). As already discussed, in the male the 2 sex chromosomes are not identical (X, Y), whereas in the female they are (XX). Various genetic mechanisms may be responsible for chromosomal abnormalities. Nondysjunction, as has been described in the *Drosophila,* implies that in spermatogenesis, oogenesis, or mitosis a chromosome pair fails to separate and enters the nucleus of the daughter cell together so that one daughter cell receives an extra chromosome at the expense of the other.

Mosaicism (chimera) means that the individual consists of cells of 2 or 3 chromosomal types. Another mechanism is simple loss of a chromosome.

Chromosomal abnormalities have been de-

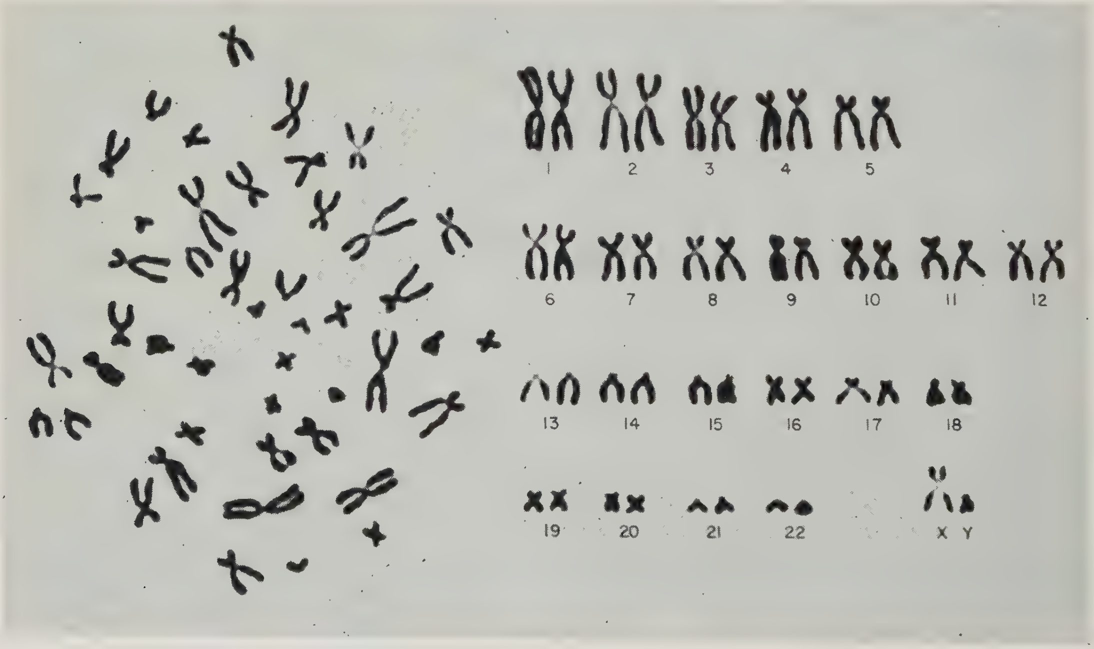

Fig. 338. Left, chromosomes of a dividing human cell at metaphase. Right, karyotype of normal human male showing 22 pairs of autosomes and XY sex chromosomes.

scribed in sexual abnormalities such as hermaphroditism, Turner's syndrome, and Klinefelter's syndrome. They have been found in mongolism, in leukemia, and in congenital defects such as achondroplasia, hemophilia, phenylketonuria, and Marfan's syndrome. Irradiated cells and tumor cells have shown an abnormal chromosomal pattern.

Methods for human chromosome analysis*

Blood culture method

1. Draw 10 ml. of the patient's blood into a sterile heparinized tube and add 0.25 ml. Bacto-phytohemagglutinin.
2. Leave the tube in iced water for 1 hr.
3. Centrifuge at 400 r.p.m. for 10 min.
4. Transfer the supernatant plasma containing the white cells in 3 ml. amounts to several 2 oz. sterile prescription bottles each containing 5 ml. tissue culture fluid.†
5. Incubate the bottles containing the cell cultures on their sides at 37° C. for 3 days. During the last 2 hr. of the incubation period, add Colcemide to a concentration of 1 μg/ml.
6. Transfer the cell culture to a clean dry centrifuge tube and centrifuge for 5 min. at about 1000-2500 r.p.m.
7. Discard the supernatant liquid.
8. Add about 7 ml. 1.12% sodium citrate to the cell deposit.
9. After 15 min. at 37° C. recentrifuge the tube at about 1000-1500 r.p.m.
10. Fix the cell deposit in about 7 ml. 50% acetic acid in water.
11. Leave the cells in this fixative for a few min.
12. Recentrifuge the tube for 5 min. at 1000 r.p.m.
13. Make routine blood films with the cell deposit on clean slides and quickly air dry them.
14. Stain the dried films in 2% aceto-orcein in 65% acetic acid, dehydrate, and mount in the routine manner.

Bone marrow culture technic

Cells suitable for chromosome analysis may be obtained by using a short-term culture technic for bone marrow based on the method of Ford et al.[15]

1. Remove the bone marrow by sternal puncture under local anesthetic and disperse approximately 0.5-1 ml. specimen into each of several sterile tubes each containing 10 ml. heparinized Ringer solution (50 units heparin/ml.).
2. Remove the Ringer solution by gentle centrifugation.
3. Resuspend the cell deposit in 3 ml. of patient's own serum.
4. Transfer this to sterile 2 oz. prescription bottles containing 5 ml. cell culture fluid.*
5. Incubate on their sides at 37° C.
6. It is usually possible to obtain sufficient marrow for several preparations. Incubate the first bottle for 5-7 hr. only. During the last 2 hr. of this period, add deacetylmethylcolchicine (Colcemide) to a final strength of 2 μg/ml. (This drug is thought to interfere with the formation of the mitotic spindle and so serves to arrest and accumulate cells in mitosis.)
7. After incubation, centrifuge the cell culture and resuspend the cells in 10 ml. 1.12% (hypotonic) aqueous sodium citrate for 20-30 min. at 37° C. The hypotonic treatment distends the cells and disperses the chromosomes throughout each mitotic cell.
8. Once again centrifuge the suspension and replace the supernatant fluid by 2 changes of 50% glacial acetic acid.
9. Fix the cells for 15 min. and resuspend in 2 or 3 drops 2% lactoaceto-orcein stain.[16]
10. Make squash preparations from this cell-stain mixture.
11. Treat the remaining bottles similarly on successive days.

Aceto-orcein stain for chromatin patterns

Reagents:

1. Fixative. Rapid fixation in equal parts of ether and absolute ethyl alcohol (EtOH) or in 95% EtOH.
2. Aceto-Orcein stock stain

Orcein	1 gm.
Glacial acetic acid	45 ml.
Distilled water	55 ml.

   (a) Heat the acid on a hot plate to 80°-85° C. Be sure to use asbestos pad.
   (b) Add the orcein, shaking rapidly or using a mechanical stirring rod.
   (c) Gradually add this solution to the distilled water (room temperature), stirring constantly.
   (d) Stopper the flask and bathe in cold running water, shaking to cool the solution.
   (e) Filter through No. 1 filter paper and store in a brown Coplin jar with a screw top. The stain improves with age.

3. Fast green stock stain

Fast green	0.03 gm.
95% EtOH	100 ml.

   (a) Add the fast green to the alcohol and stir to dissolve.

Procedure:

1. Run the slide through 50% EtOH, 5 dips and distilled water, 5 dips.
2. Place the slide in aceto-orcein stock stain for 5 min.
3. Wash for 10 sec. with distilled water in a gentle wash bottle stream.
4. Dehydrate in 50, 70, 80, and 95% EtOH, 5 dips each.

---

FUNCTIONS OF SPLEEN

The general conception of the function of the spleen is that it is a reservoir or bank of blood. In fetal life erythropoiesis begins in the spleen, but the main function of the spleen is that of lymphopoiesis. The spleen is concerned with the destruction of worn-out red cells, leukocytes, and blood platelets, and also assists in the destruction of protozoa and foreign material. The destruction within the sinusoids is brought about by sequestration, i.e., separation, collection, and stasis of the to-be-destroyed tissues. The next step is phagocytosis by the reticuloendothelial system or destruction by lysis. The latter process produces swelling of the affected cells which then rupture and disintegrate. The lytic destruction of red blood cells thus releases iron which is either reutilized or stored in the spleen.

Since the spleen is part of the lymphatic system, it participates with it in the alarm (stress) reaction and in the production of gamma globulins and antibodies. It has been suggested that lack of resistance to infection follows splenectomy. The spleen may also be involved in the production of a coagulation factor of globulin nature.

In fetal life myeloid cells are also produced in the spleen. In the adult, under pathologic conditions, this fetal function is reactivated and gives rise to foci of myeloid metaplasia in the spleen.

This organ contains more endothelial tissue than any other organ of the body. In adult life lymphocytes are produced by the malpighian corpuscles. Many investigators believe that monocytes and reticuloendothelial cells arise in the spleen largely because of its abundant reticuloendothelial structure. It is also probable that the spleen exercises some sort of control over the bone marrow. Splenectomy is often followed by the appearance in the peripheral blood of nucleated red cells, Howell-Jolly bodies, basophilic cells, and reticulocytes, together with an increase in the number of platelets. Following splenectomy, there is also a great increase in the number of leukocytes, platelets, and red blood cells. It is the appearance of Howell-Jolly bodies, however, that is the most characteristic phenomenon following splenectomy.

Not only surgical but also physiologic and pathologic removal of the spleen, as may occur after extensive infarction, hypoplasia, aplasia, or calcification of the spleen, is followed by increases in all blood cellular elements or in 1 or 2 series only.

Whereas splenectomy is at times followed by an increase in all of the cellular components of the peripheral blood, splenomegaly or hyperplasia of the spleen is frequently accompanied by neutropenia, thrombocytopenia, or anemia or by all 3, **splenic pancytopenia.** There is thus some evidence that the normal spleen controls the production of cells in the bone marrow and that the removal of the spleen at times leads to unrestrained proliferation of the marrow elements, whereas hyperplasia leads to splenic hyperfunction and bone marrow depression. The mediating factor is probably humeral in nature and is produced by the reticuloendothelial system. Besides the humeral factor, other elements may play a role. Increased phagocytic activity may be responsible for the production of anemia but may also affect platelets and white blood cells. Also, a hemolytic antigen-antibody mechanism (hemolysins, etc.) may be responsible for decreased survival time of one or all of the corpuscular blood elements, which are thus more rapidly destroyed in the spleen. Finally, the existence of a toxic factor produced in the spleen has been postulated which may be responsible for the bone marrow depression.

It must be stated that splenic changes are not always accompanied by hematologic alterations so that, for instance, posttraumatic surgical removal of the spleen is frequently not followed by any or by only very transient hematologic changes.

FUNCTIONS OF BLOOD

The chief functions of the blood are to transport food materials to the tissues, to carry oxygen from the lungs to the tissues and carbon dioxide from the tissues to the lungs, to carry waste materials from the tissues to the excretory organs, to transport endocrine secretions from one organ to another, to act as a defense mechanism against infection through the activities of certain white cells and immune bodies developed in the blood stream, to assist in maintaining a constant water balance and correct osmotic equilibrium in the tissue cells, and, further, to assist in the maintenance of a constant body temperature and to maintain a degree of irritability of the tissue cells so that functional activity may be carried on satisfactorily.

Chapter 60

Composition and physiology of the blood

JOHN D. BAUER

The circulating blood normally consists of a suspension of blood cells of different kinds in a fluid element called plasma. The formed elements are erythrocytes, leukocytes, and blood platelets. Plasma is the liquid portion of blood of a very complex composition: water, proteins, carbohydrates, lipids, electrolytes, other mineral salts, hormones, antibodies, and enzymes. If blood is allowed to clot, fibrinogen is removed from the plasma, and the remaining fluid is called blood serum.

The total volume of the blood comprises about 6 to 8% of the body weight in adults.

There are normally from 4,600,000-6,200,000 red blood cells/c.mm. in the adult male (average 5,400,000) and from 4,200,000-5,400,000 in the adult female (average 4,800,000). There are from 5,000-10,000 leukocytes normally, with an average of 7000-8000/c.mm. The number of blood platelets varies from 200,000 to 300,000/c.mm. of blood according to some authorities, and is higher in men than in women and children.

RED BLOOD CELLS OR ERYTHROCYTES

The normal red blood cell or erythrocyte is a circular to slightly oval biconcave disc with an average diameter of 7.2μ. It is orthochromatic. It is bright yellow with a central depression, is highly light-refractile, and apparently is homogeneous. The red cell in the circulating blood is normally nonnucleated. Red cells originate in the bone marrow. Jordan and Baker held that the red cells are released into the circulation through gaps in the endothelial walls of the capillaries.

Table 224 includes some of the attributes of red blood cells.[18]

Table 224. *Physical measurements of red blood cells*

Red blood cells	*Average*	*Range*
Diameter	7.5μ	7.2-7.8μ
Thickness	2.0μ	1.7-2.2μ
Volume	87.0 c.μ	70-94 c.μ
Hemoglobin content	29 $\mu\mu$g	23-35 $\mu\mu$g

The biconcave shape is partly determined by the tension of the cell membrane and partly by the cell contents. The presence of abnormal hemoglobins may change the shape of the red cells. It is the stroma (structural protein) to which the hemoglobin is attached and which forms the elastic, selectively semipermeable cell membrane.

FATE AND PHYSIOLOGY OF RED BLOOD CELLS

Many different methods have been used to estimate the average life span of the human red blood cell. Callender et al.,[19] using Ashby's differential agglutination method[20, 21] in Rh-positive men,[22] concluded from a mathematical analysis of their data that red blood cells live for approximately 120 days. Measurement of the time required for the disappearance of sulfhemoglobin from the blood of cyanosed workers[23] indicated the life span of the red blood cells to be 115 days. Shemin and Rittenberg[24] reported their results in estimating the life span of the red blood cell by estimating isotope concentration of the hemin at various periods in experimental works. They showed that the heme of the nonnucleated red blood cells, unlike the constituents of nucleated cells, is not continuously formed and degraded within the cell. The red cells are not indiscriminately destroyed, but their rate of destruction is a function of the age of the cell. Study of the isotope concentrations found in the heme of the human red blood cell, after the feeding of glycine labeled with N^{15}, indicated that the erythrocyte is not subjected to indiscriminate destruction but has a life span. This was found to be about 127 days.

If it is assumed that the life span is 120 days, and if the estimate is 5,000,000 red cells/c.mm. of blood, the bone marrow would have to manufacture about 250 billions of red cells every day. This means a production of 42,500 red cells for each c.mm. of blood each day. About 0.83% of the red cells and hemoglobin are replaced daily.

Returning to the question of the origin of erythrocytes, according to the Schilling idea, the formation of these cells begins as indifferent erythrogonia, followed by the proerythroblast with nucleoli, then by typical hemoglobin-containing macrocytic erythroblasts, and then polychromatic and orthochromatic smaller normoblasts. Then, in turn, come the denucleated polychromatic cells and, finally, the full-grown orthochromatic normocytes. There are many explanations of the denucleation of the erythrocyte. First, Maximow claimed that the expulsion is seen in the embryonic body although this is denied by Schridde. Albrecht is in favor of the expulsion theory. A second theory is that of karyorrhexis, in which the pyknotic nucleus assumes bizarre shapes and is dissolved into spherical sections, leaving the cell gradually. Weidenreich[25] maintained that karyorrhexis may go on to further reduction, giving the appearance of small chromatin rodlike changes. Next, there is a theory of intracellular nuclear disintegration, which is largely the belief of Naegeli.

It is interesting to note the remarkable amount of basophilic substance in the young forms of the erythrocytes and also to note when hemoglobin is first seen in embryonic blood. Wulf claims to have seen traces of hemoglobin by means of the spectroscope in the embryo with 9 primary segments. The hemoglobin shows up first in the mitochondria, which are found in the youngest cell. In this connection, study of polychromasia by supravital staining methods shows that it may degenerate into basophilic punctation. In other words, polychromatic vital-staining reticular substance and basophilic punctation are protoplasmic and not nuclear phenomena. Normally, polychromasia is seen in peripheral blood in the proportion of 0.2-1% of all red cells. Pathologically, this may range as high as 50%, as seen in the anemias and the after effects of acute infections, of malaria, and of tuberculosis, in blood crises of pernicious anemia, and in hemolytic icterus.

Erythropoiesis

Physiologic processes which may affect erythropoiesis are menstruation and pregnancy, hemorrhage, and blood destruction. There is a rapid production of red cells after venesection, first, in the form of migrating maturing forms and, second, as nucleated elements, immature polychromatic erythroblasts, and normoblasts. At this time, liberation of many young forms takes place. Any decrease in the quantity of erythrocytes is regarded as a physiologic stimulant to the formation of more erythrocytes. However, daily blood transfusions in quantity equal to the destroyed blood lead to inertia of the destroyed bone marrow and aplasia. A single injection of a physiologically destroyed amount of erythrocytes results in immediate irritation of the bone marrow. This irritation may be followed within 4-7 days by prolonged increased erythropoiesis. Lack of oxygen may also be an effective physiologic stimulant, such as is seen in high altitudes. Increase in the number of erythrocytes due to chronic lack of oxygen is seen in heart diseases, congenital pulmonary stenoses, and mediastinal tumors. Hypernephromas, cerebellar tumors, hemangioblastomas, and ovarian tumors are known to be associated with polycythemia.

The humeral control of erythropoiesis is generally accepted. Linman and Bethell[26] described 2 erythropoietic plasma factors which differ chemically and physiologically. One factor, a nondialyzable mucoprotein which is relatively thermolabile and ether insoluble, is apparently responsible for the initial proliferation of the hematocytoblast or proerythroblast to differentiate and to form hemoglobin. This factor is called **erythropoietin.** It appears to depend upon good kidney function. The second plasma factor, thermostable and ether soluble, is not a protein and is responsible for the second phase of erythropoiesis, the proliferation of normoblasts within the bone marrow and is found in patients with primary and secondary polycythemia. The first factor essentially controls the hemoglobin synthesis, whereas the second factor increases the number of red blood cells without increasing hemoglobin formation. The second factor appears to be independent of kidney function.

Hypoxia (or the relationship of oxygen supply to tissue requirements) is the main stimulus to erythropoiesis. How and where hypoxia or any other erythropoietic stimulus acts is not certain. Experimentally, the bone marrow, stomach, kidney, liver, and spleen can either be ruled out as the site of production or can be used to prove that there are several types of erythropoietic substance. This substance can be found in the urine of severely anemic patients, and there is increasing evidence, as already stated, that intact kidney function is related to erythropoiesis.

Erythropoiesis proceeds according to a regular predetermined pattern and rhythm in erythroblastic nests within the bone marrow, forming what has been called **living erythrons.** The youngest early precursor cell (proerythroblast) divides hemihomoplastically, giving rise to 2 smaller erythroblasts, one of which again forms an early erythroblast, whereas the other divides progressively into 2, 4, and 8 normoblasts. On the basis of nuclear volume measurements of the cells of the erythron, Weicker assigned a given nuclear volume to each cell type and originated the karyometric method of cell classification (p. 1068).

Functions of erythrocytes

The physiologic functions of the erythrocytes include (1) gas exchange, the transport and release of oxygen and of carbon dioxide, (2) participation in the buffer system of the blood, and (3) a role in the clotting mechanism, according to Quick, mentioned in the discussion on coagulation.

Respiration

The red blood cell accepts oxygen and releases CO_2 in the lung capillaries. It then transports the gases from the lung to the tissues. Transport is made possible by the ability of hemoglobin to combine reversibly with oxygen, as represented by the following equation:

$$\text{Hb} + \text{O}_2 \rightleftarrows \text{HbO}_2$$

Hb = reduced hemoglobin
HbO_2 = oxyhemoglobin

The degree of saturation of hemoglobin with oxygen depends on the CO_2 tension which can be shown to determine the shape of the dissociation curve. If the oxygen tension is high ($p - O_2$ 100 mm. Hg as it is in arterial blood), hemoglobin is about 95% saturated. If the oxygen tension falls, oxygen is rapidly released. In addition to the CO_2 tension, the dissociation curve is influenced by such factors as temperature and electrolytes. Oxygen is carried only by the intracellular hemoglobin, whereas carbon dioxide is carried by hemoglobin and plasma.

Buffering action

Oxyhemoglobin is a stronger acid than reduced hemoglobin. At a constant pH, a larger amount of alkali is necessary to neutralize oxyhemoglobin than reduced hemoglobin. When oxygen is released at the tissue level, alkali is also released to neutralize the carbonic acid formed in the interstitial fluid in the presence of CO_2.

In the lung, where CO_2 is given off, the freed alkali is taken up again by hemoglobin. The intracellular hemoglobin is responsible for 60% of the buffering ability of the blood. This result is achieved by the **chloride shift,** which allows chloride to leave the red cell whenever the CO_2 tension falls and allows bicarbonate to enter the cell. This is a reversible process so that chloride enters the cell when the CO_2 tension increases, and bicarbonate is released in exchange for chloride (Hamburger phenomenon).

The chemical composition and metabolism of the red cell have important bearing on various blood diseases.

The cell membrane is impermeable to sodium and potassium but allows the entry and release of hydrogen, bicarbonate, and chloride ion. The erythrocyte, therefore, contains more potassium than sodium. The retention of potassium represents a vital, energy-requiring process of the cell utilizing glucose as an energy source. The enzyme system acetylcholine cholinesterase I functions as a guard against changes in permeability of the cellular membrane.

In the breakdown of glucose, the first step is the formation of glucose 6-phosphate. In the course of aerobic glycolysis, this product is broken down to citric acid which is degraded to carbon dioxide in the Krebs cycle. The anaerobic glycolysis which provides the main source of energy metabolizes glucose 6-phosphate to pyruvic and lactic acids (Embden-Meyerhof scheme). Pyruvic acid is decarboxylated to acetic acid which enters the citric acid cycle of Krebs. In anoxemic newborn infants and in premature babies the complete breakdown of lactic acid to carbon dioxide and water is often not accomplished so that the accumulated lactic acid leads to acidosis. An alternate pathway of the metabolism of glucose 6-phosphate is the direct oxidation to 6-phosphogluconate by the action of glucose 6-phosphate dehydrogenase. Deficiency of this enzyme leads to defective direct oxidation of glucose in red cells and to such phenomena as Heinz body formation and primaquine type of hemolytic anemia.

Hemolysis

The factors controlling hemolysis are poorly understood but are related to the activity of the reticuloendothelial system. The mechanisms of hemolysis will be considered in the discussion of hemolytic anemias.

HEMOKONIA

In the dark-field preparation, one finds **hemokoniae,** which are fine dustlike particles with brownian movement. Neumann[27] considers these bodies fatty particles and notes that they are prevalent particularly after eating. They are not cells but may be degradation products of cells.

HEMOGLOBIN

Hemoglobin is the red iron-bearing protein contained within the erythrocytes in normal blood. Its major function in the normal individual is as a carrier of oxygen from the lungs to the tissues where it readily releases this oxygen to the tissues and then returns to the lungs to combine with more oxygen. This respiratory function of hemoglobin is vital to the life of all cells. Although not all of the physicochemical aspects of hemoglobin have been established, certain basic facts are generally accepted: Hemoglobin consists of 4 heme molecules conjugated with 1 globin molecule. The heme molecule represents the colored component of the hemoglobin molecule. The globin fraction is a complex protein with a molecular weight between 63,000 and 67,000. The source of globin is protein in the diet, which is broken down in the gastrointestinal tract to amino acids of various types, which in turn are absorbed and used in hemoglobin synthesis. Although some of the amino acids found in globin have been identified as arginine, histidine, lysine, tryptophane, and tyrosine, it is believed that no one single amino acid is alone essential for hemoglobin synthesis. Orten and Orten[28] have demonstrated that, if any one of the essential amino acids is added to the diet, there is no increase in hemoglobin synthesis. The amount of dietary protein required to keep the body in satisfactory equilibrium so far as hemoglobin synthesis is concerned is approximately 1 gm./kg. body weight. Whipple,[29] in his classical experiments, demonstrated that if protein is not obtained from outside the body in the diet, then the body will selectively take protein from tissue in order to synthesize hemoglobin: "the body guards jealously the fabrication of the hemoglobin, and given a need for both plasma protein and hemoglobin, the protein flow favors hemoglobin synthesis."* Practical use of this was made in the care of the wounded under the program known as Reparative Surgery during World War II.[30-34]

Not only will inadequate food intake affect the amount of hemoglobin formed, but also poor absorption of this protein from the gastrointestinal tract will affect the amount of hemoglobin absorbed; therefore, such gastrointestinal affections as protracted diarrhea in colitis, atrophic gastritis, and other conditions will result in hemoglobin deficiency. There is present in the gastrointestinal tract intrinsic factor and erythrocyte maturation factor which affect hemoglobin formation. In some unknown way these factors are related to the fabrication of hemoglobin through the intermediary role of the liver prior to the taking up of the substances in the bone marrow by the red blood cells.

Variations in the composition of the globin component are responsible for the appearance of abnormal human globins. The protein composition is genetically determined, and these changes are part of the expressions of gene mutations. The heme component is the same in all hemoglobin. (For details see discussion of abnormal hemoglobins.)

The 4 heme molecules of hemoglobin consist of 4 protoporphyrin molecules containing ferrous iron. Although iron is important in the synthesis of hemoglobin, exceedingly small amounts are required in the diet for normal hemoglobin synthesis.

Hemoglobin consists of 4 heme molecules chemically identified as ferrous protoporphyrins. The chemical alignment of these porphyrins in relation to globin in the formation of hemoglobin has been extensively studied by Pauling.[35]

The protoporphyrin is formed in the bone marrow erythroblasts out of glycine and succinate. Though the biosynthesis of porphyrin will be discussed later, it should be mentioned that one of the intermediary products, delta-aminolevulinic acid, is also used for the synthesis of vitamin B_{12}. Vitamin B_6 and panto-

thenic acid are required for the production of delta-aminolevulinic acid.

The iron required for this hemoglobin synthesis from the **diet alone** is almost infinitesimal, being perhaps approximately 12 mg. as the daily average minimum requirement. This amount is readily available from any average diet; it requires an unusually subnormal diet to bring iron intake to levels lower than this. The reason for this is that the iron stored within the body is not depleted unless there is loss through recurrent hemorrhage or a great increase in demand such as occurs in early childhood, during the growing period, and in pregnancy. When extra iron is needed, it may be given in the form of iron salts which are absorbed from the gastrointestinal tract in the ferrous state. Under unusual circumstances, parenteral iron therapy may be necessary to supply the depleted iron stores of the body.

Iron absorption is aided by reducing substances such as ascorbic acid. The role of hydrochloric acid is not quite clear though studies by Moore fail to show that ionization of iron produced by hydrochloric acid has any stimulating effect on iron absorption. The iron absorption is influenced by the state of the iron stores, and the rate of erythropoiesis. Iron absorption is increased if the iron stores are reduced and if erythropoiesis is stimulated. Iron metabolism is considered in detail in the discussion of iron deficiency anemia.

Iron combines in the small intestine with a protein, forming **ferritin.** It is then released from the mucosal cells of the small intestine to the plasma, where it has been shown that β_1 globulin carries the iron in combination known often as **transferrin.** Associated with this globulin, it is transported to the bone marrow where the iron combines with protoporphyrin to form heme. The iron is transferred from reticulum cells to erythroblasts by the process of pinocytosis. The heme then combines with globin to form hemoglobin.

Breakdown of hemoglobin

If hemoglobin is liberated from the red cells, it is immediately broken down. Normally, hemoglobin is broken down in the reticuloendothelial system where the heme portion of the hemoglobin molecule is transformed to nonconjugated bilirubin which is ultimately conjugated by the liver and excreted. The iron is retained and reutilized for the production of hemoglobin and other iron-containing porphyrins such as cytochromes and myoglobins. The globin moiety is also retained and split into its amino acid components, which are reutilized.

Intravascular lysis, which is usually a pathologic process, produces free hemoglobin which unites with haptoglobin and either remains in the serum, or, if the concentration is high, is excreted by the kidney. Some of it is also taken up by the reticuloendothelial system and is converted to free bilirubin.

The breakdown of hemoglobin is considered in detail in the discussion of hemolytic anemias.

Hemoglobin normally is in the state in which it has absorbed oxygen and is known as **oxyhemoglobin.** Oxyhemoglobin can be identified in the spectroscope by the 2 intense absorption bands at 578 and 540 mμ.

Technic of spectroscopic examination of hemoglobin:

1. Dilute 1 part blood or washed red cells with 100 parts water or with 100 parts 1% sodium hydroxide.
2. Observe 2 absorption bands through the spectroscope; 1 band will be in the yellow zone and 1 in the green zone.
3. Addition of a few crystals of potassium ferrocyanide converts oxyhemoglobin into methemoglobin which has only 1 absorption band at 630 mμ.
4. Addition of ammonium sulfide to the original oxyhemoglobin solution produces reduced hemoglobin with only a single band in the yellow and green zones.

Abnormal forms of hemoglobin

Methods for the determination of hemoglobin are described in Chapter 61.

Methemoglobin[36, 37]

Methemoglobinemia is a disease characterized by a temporary or permanent increase in methemoglobin in the red blood cells. Clinically it leads to cyanosis since there is interference with the oxygen transport. If over 1.7% of the total hemoglobin is present as methemoglobin, cyanosis will occur. Clinically, this cyanosis must be differentiated from the cyanosis produced by acquired or congenital heart and lung diseases (anoxia) and by polycythemia. Unless a hemolytic process is present, methemoglobin is always confined to the red blood cells.

There are 2 types of methemoglobinemia: acquired and congenital (hereditary).

Acquired methemoglobinemia is usually associated with intoxication with chlorates, nitrites, nitrobenzol, aniline, hydrogen sulfide, and other chemical agents. It may be caused by exposure in industry to excessive amounts of these agents or may result from excessive intake of drugs, or it may result from idiosyncrasies to certain drugs, such as acetanilid and sulfanilamide.

Methemoglobinemia is also caused by overproduction or excessive absorption of nitrites which may be derived from the intestines in constipation or diarrhea of long duration, or these nitrites may be contained in the drinking water obtained from a well. Acquired methemoglobinemia is frequently associated with sulfhemoglobinemia due to the fact that intestinal bacteria may produce a large amount of hydrogen sulfide, some of which may be absorbed.

The relationship of methemoglobin to Heinz body formation will be considered in the discussion of Heinz bodies. As methemoglobinemia is apparently a cause of abortion in cattle, some attempts have been made to prove its responsibility for some cases of human abortion.

In hemolytic anemias, methemoglobin may be present in the plasma, usually combined with methemalbumin. This form of methemoglobinemia is considered in the discussion of hemolytic anemias.

Congenital methemoglobinemia, a hereditary disease, has all the characteristics of methemoglobinemia—cyanosis varying in shade and intensity and methemoglobinemia—and in addition a hereditary background. It is inherited as a recessive character and is due to the absence of intraerythrocytic enzymes which mediate the reduction of methemoglobin. The enzyme involved is probably coenzyme factor I (diaphorase I). Methemoglobinemia is thus essentially a mendelian recessive enzyme deficiency disease. It is at times combined with a dominant type of molecular hemoglobin abnormality, hemoglobin-M disease, which, as all the hemoglobinopathies, involves the protein moiety of the hemoglobin molecule.

Laboratory test for methemoglobinemia—spectroscopic examination:

1. Dilute 1 part blood or washed red cells with 100 parts distilled water or with 100 parts 1% sodium hydroxide. Examine without delay because methemoglobin may be formed spontaneously on standing. Examine with the spectroscope. If **methemoglobin** is present, a band will appear at 630 mμ. **Sulfhemoglobin** will produce a single band which with the usual spectroscope cannot be distinguished from the methemoglobin band.
2. Add a few drops 5% solution potassium cyanide, and if the band is due to methemoglobin, it will disappear. The sulfhemoglobin band will remain.
3. Add 2 or 3 drops 3% hydrogen peroxide. Methemoglobin or sulfhemoglobin bands will disappear.

Methemoglobin in acquired methemoglobinemia quickly disappears from the circulation after exposure to the causative agent has ceased.

Carboxyhemoglobin

Carboxyhemoglobin (carbon monoxide hemoglobin) results from a combination of hemoglobin and carbon monoxide. It has been claimed that hemoglobin has 200 times the affinity for carbon monoxide that it has for oxygen. Carboxyhemoglobin is found in the blood after exposure to inhalation of artificial gas, automobile exhausts, underground gas collections, or other agents containing carbon monoxide. It is believed that life can be maintained with a 20% concentration of carbon monoxide hemoglobin, but that a concentration of 50% or greater will result in death.

Carboxyhemoglobin may be identified by spectroscopic examination. It must be remembered that the bands are at 572 and 535 mμ, which are very close to those of oxyhemoglobin. Sunderman has suggested the following spectroscopic test.

Sunderman dithionite spectroscopic test:

1. Dilute the blood with water until the 2 bands in the spectrum of both carbon monoxide hemoglobin and oxyhemoglobin are still clear but faintly visible.
2. Add 5 mg. dithionite ($Na_2S_2O_4$).
3. Mix gently and examine for persistence of the bands of carboxyhemoglobin. If 2 bands persist, carboxyhemoglobin is present.

Other tests are given in the section on Toxicology.

Sulfhemoglobin

Sulfhemoglobin is an abnormal hemoglobin, the exact chemical structure of which is unknown. Sulfhemoglobinemia often accompanies methemoglobinemia. Sulfhemoglobinemia has been described in patients who habitually take alkaline bromides as a headache remedy and in others who have either been exposed to large doses of phenacetin or sulfonamides or have idiosyncrasies to these drugs.

The differentiation of methemoglobin and sulfhemoglobin is considered in the discussion of methemoglobinemia. It has been stated that methemoglobin quickly disappears from the circulation after exposure to the causative agent has ceased, whereas sulfhemoglobin persists for several weeks and is destroyed at the same time as the involved red blood cells.

Sulfhemoglobin shows a main spectroscopic absorption band at 618 mμ. It is found in both the red blood cells and the plasma. Unlike methemoglobin, addition of 5% cyanide (KCN) will not cause the band to disappear. Sodium dithionite ($Na_2S_2O_4$) also will leave the band unchanged. Sodium sulfite and carbon monoxide will leave the band unchanged, but sodium sulfite with sodium hydroxide added causes disappearance of the band as does 3% hydrogen peroxide.

The inherited abnormalities of the hemoglobin molecule are discussed in Chapter 64.

Myoglobin

Myoglobin or **myohemoglobin** in the urine has been described in relation to muscle injury. Detection of myoglobin in the urine must be made within 8-12 hr. after the injury since the pigment tends to disappear after this time. Myoglobin is excreted by the kidneys at the slightest increase of its plasma level. In contrast to hemoglobin, myoglobin is not bound to haptoglobin, but it may be bound to some other serum protein.

Tests for myoglobinuria[38]

Spectroscopic examination

Sunderman and associates recommend examining urine for absorption bands at 582 and 542 mμ. Since these bands are very close to those of oxyhemoglobin, it is impossible to make a positive diagnosis by the spectroscope alone though fluorescent light is helpful.

Dithionite test

Add 10 mg dithionite to 10 ml. urine and place in a 9 collodion filter.*

If hemoglobin is present, a clear filtrate is obtained, whereas in the presence of myoglobin a brown filtrate with an absorption band at 583 mμ is obtained.

Differential solubility test

At 80% saturation with ammonium sulfate hemoglobin in solution is completely precipitated from the solution along with denatured myohemoglobin, but only minor amounts of undenatured myohemloglobin are included. At 100% saturation myoglobin is completely precipitated together with normally occurring urinary pigments. Prior to the test, the protein nature of the dissolved hemoglobin or myoglobin is to be proved by the sulfosalicylic acid test. Both these pigments also give the benzidine reaction.

Procedure:

1. To 1 ml. urine add 3 ml. 3% sulfosalicylic acid. Mix and filter. If the pigment is precipitated it is a protein.
2. To 5 ml. urine add 2.8 gm. ammonium sulfate and mix. Filter. If the filtrate is of abnormal color, myohemoglobin is present.

PORPHYRIA AND PORPHYRINURIA[39, 40]

Hemoglobin, as already stated, is an iron porphyrin because an iron atom is incorporated into the porphyrin structure. A porphyrin consists of 4 pyrrole rings linked to each other by methylene bridges. Each porphyrin has 8 substituent positions which allow the attachment of side chains. The type and symmetry of arrangement of the side chains distinguish the various types of porphyrins. Hemoglobin synthesis is based on a complete synthesis of protoporphyrin. Not all porphyrin is used in hemoglobin production so that a small amount of free porphyrin and coproporphyrin can be found within the red blood cells. This substance is called free erythrocyte protoporphyrin and coproporphyrin.

Normal values of protoporphyrin in mature erythrocytes range from 20-50 gamma/100 ml. cells. These values are increased to 150-350 gamma in lead poisoning, cirrhosis, iron deficiency, and congenital porphyria; they are decreased or normal in pernicious anemia. Red blood cells containing much erythrocytic protoporphyrin fluoresce under ultraviolet light. Free coproporphyrin in the red blood cell corresponds fairly closely to the reticulocyte level, which, as will be seen later, is a good indicator of red cell maturation or hemoglobinization.

Biosynthesis of porphyrins

Glycine plus active succinate derived from Krebs tricarboxylic acid cycle or from DPN give rise to delta-aminolevulinic acid. This production is dependent on an adequate supply of pyridoxine. Two molecules of delta-aminolevulinic acid form porphobilinogen. This process is catalyzed by copper-containing enzymes. Porphobilinogen is then converted into uroporphyrinogen III. The latter substance is enzymatically transformed to coproporphyrinogen III. An enzyme converts

Fig. 339. Outline of porphyrin synthesis. (Based on data from Harper, H. A.: Review of physiological chemistry, Los Altos, Calif., 1961, Lange Medical Publications; from Bauer, J. D., Toro, G., and Ackermann, P. G.: Bray's clinical laboratory methods, St. Louis, 1962, The C. V. Mosby Co.)

coproporphyrinogen III to protoporphyrin. In the production of heme, ferrous iron is incorporated into protoporphyrin. The term **porphyrinogen** is used to describe the reduced forms which can be oxidized to porphyrins. The term **type III** indicates a porphyrin with asymmetrical substitution, whereas the term **type I** characterizes a porphyrin with symmetrical arrangement of the substituents. These substituents are in the case of uroporphyrins acetate and proprionate and in the case of coproporphyrins methyl groups and proprionate. Under circumstances which are as yet not well understood, enzymatic transformation of porphobilinogen into uroporphyrin I occurs which then gives rise to coproporphyrin I.

The term **porphyria** embraces certain hereditary and familial conditions in which there is an increased excretion of coproporphyrins and uroprophyrins in urine, feces, or both.

The term **porphyrinuria** includes many conditions such as poisoning by heavy metals, blood diseases, etc., which lead to an increased excretion of coproporphyrins in the urine.

Porphyrias reported from South Africa and Turkey that are clinically and biochemically reminiscent of the congenital type of porphyria but that are, in fact, due to exposure to poisons made it advisable to review the classification of porphyrias.

Watson suggested the following classification of porphyrias.

Classification of porphyrias (Watson)[41]

I. Porphyria erythropoietica (recessive)
II. Porphyria hepatica
    A. Hereditary acute intermittent (dominant)
        1. Manifest
        2. Latent
    B. Hereditary mixed or variegate group (dominant)
        1. Cutaneous with little or no acute manifestations

  2. Acute intermittent without cutaneous symptoms
  3. Various combinations
  4. Latent

C. Hereditary cutaneous

D. Constitutional or idiosyncratic (porphyria cutanea tarda)
  1. Chemicals, especially alcohol
  2. Idiopathic
  3. With systemic diseases

E. Acquired
  1. Secondary to hepatoma
  2. Secondary to fungicides as in Turkish epidemic

Characteristics of some porphyrias

Porphyria erythropoietica: This is a mendelian recessive and is characterized by light sensitivity. Uroporphyrin I and coproporphyrin I are produced in excessive amounts. The defect may lie in the enzymatic transformation of porphobilinogen. Porphyrin is increased in the marrow, which is the site of the metabolic defect.

Porphyria hepatica:

Hereditary acute intermittent: This is a familial disease characterized by excessive amounts of porphobilinogen, uroporphyrin III, and coproporphyrin III in the urine. The genetic defect may lie in an enzyme system of the liver, involving the production of aminolevulinic acid although an added nongenetic defect may determine the exact nature of the released porphyrin.

Hereditary mixed or variegate type: This disorder is hereditary and nonsex-linked. During acute attacks there are increased porphobilinogen and increased porphyrins which may be uroporphyrin or coproporphyrin type I or type III. There may or may not be light sensitivity.

Hereditary cutaneous: In this disorder there is light sensitivity, and urinary porphyrins, porphobilinogen, and delta-aminolevulinic acid are increased. Fecal porphyrins are not increased.

Constitutional or idiosyncratic porphyria (porphyria cutanea tarda): Excessive amounts of porphobilinogen, coproporphyrin, and uroporphyrin are eliminated in the stool, with bile. During attacks, coproporphyrins and uroporphyrins appear in the urine, but there is little porphobilinogen in the urine.

Acquired porphyria: Acquired porphyria is characterized by coproporphyrinuria due perhaps to an enzymatic defect that affects incorporation of iron into protoporphyrin.

Quantitative estimation of porphobilinogen and porphyrins in urine*

Reagents:

1. Anhydrous sodium carbonate.
   5 gm. in container for collection of 24 hr. urine specimen.
2. Saturated sodium acetate.
   60 gm. sodium acetate in 60 ml. boiling water.
3. Ehrlich reagent.

p-Dimethylaminobenzaldehyde .	0.7 gm.
Concentrated HCl	150 ml.
Distilled water	100 ml.

4. Buffered acetic acid solution.
   1 part of saturated sodium acetate to 4 parts glacial acetic acid.
5. Ethyl acetate, N.F.
6. Sodium acetate, 3%.
   30 gm. sodium acetate/L. of aqueous solution.
7. Alcoholic iodine solution, 1%,
   1 gm. iodine crystals/100 ml. 95% alcohol. Keep in a refrigerator in brown bottles.
8. 1.5N HCl (5%).
   5 ml. concentrated hydrochloric acid in water and diluted to 37 ml. with water.
9. Butyl alcohol. Normal, A.R.
10. Aluminum oxide.
    Most lots are satisfactory, but each lot should be tested to make sure it absorbs uroporphyrins since occasionally a lot is found which will not do so.
11. Acetone, G.P.
12. 50% acetone in 1% acetic acid.

Acetone	250 ml.
Water	245 ml.
Concentrated glacial acetic acid	5 ml.

13. Glacial acetic acid, A.R.
14. Acetic acid, 1%.
    1 ml. glacial acetic acid q.s. to 100 ml. with water.
15. Coproporphyrin standard.
    10 μg/100 ml.

Collection of specimen: Collect a 24 hr. urine specimen in a bottle containing 5 gm. sodium carbonate. Upon receipt, measure the urine volume and record the quantity.

Measure and record the pH of the specimen. If it is not above pH 6.0, the specimen may be processed, but a note should be made in the final report to the effect that the urine was not alkaline upon receipt. It is the function of the sodium carbonate in the collection bottle to keep the urine at an alkaline pH in order to prevent destruction of porphyrins and to inhibit the conversion of porphobilinogen to porphobilin since the latter will give a negative reaction with Ehrlich aldehyde reagent.

These methods are modifications of the technics of Watson and Schwartz. The procedures were adapted to be of practical utility in clinical laboratories in which elaborate equipment may not be available.

Apparatus:

1. Coleman* catalog No. 12-190 photofluorometer cuvets.
2. Coleman model 12C photofluorometer.
3. Coleman filters, catalog No. 12-224 (primary) and No. 14-220 (secondary).
4. Coleman spectrophotometer or Galv-O-Meter.
5. Coleman catalog No. 12-057 connecting cable.
6. Separatory funnel, 250 ml.
7. Graduates, 50 ml. and 500 ml.
8. Chromatograph tube, No. C-4080 (size 2, 19 × 200 mm.).†
9. Suction flask, 500 ml.
10. Sea sand, washed.
11. Portable ultraviolet inspection lamp.
12. Pipets calibrated, 5 ml.
13. Pipets, transfer, 0.1 ml.

Determination of porphobilinogen

Principle: Porphobilinogen is the monopyrrolic precursor of uroporphyrin, coproporphyrin, and protoporphyrin. It reacts with Ehrlich aldehyde reagent (paradimethylaminobenzaldehyde) to form a red color.

Porphobilinogen should be tested for in a freshly voided urine specimen (when available) and also in a 24 hr. specimen. The fresh specimen should first be cooled to room temperature in order to prevent the so-called warm aldehyde reaction, giving a false positive result.

Procedure:

1. Into a No. 6-304 (19 × 150 mm.) Coleman cuvet measure the following; then mix and observe.
   (a) 2.5 ml. urine.
   (b) 2.5 ml. Ehrlich aldehyde reagent.

If porphobilinogen is present, a pink to red color will usually appear at this stage.

2. Add 5 ml. saturated solution sodium acetate and shake. This reagent will convert the hydrochloric acid present in Ehrlich reagent to a weak acid, and when tested with Congo red paper, the paper will remain red. At this point any red color formed in step b above may deepen in intensity. If the color produced is very intense the test should be repeated using 2.5 ml. **quantitatively water-diluted** specimen of urine. Ordinarily, any color due to urobilinogen does not develop until the sodium acetate is added.
3. Add 5 ml. butyl alcohol and shake vigorously. Butyl alcohol will rise to the top and carry with it urobilinogen and various nonspecific Ehrlich-reacting substances, leaving the porphobilinogen in the lower aqueous layer. If the separation is not clear-cut on standing, filter through a moistened coarse filter paper.
4. *Interpretation:* The absence of a pink or red color in the aqueous (lower) phase constitutes a negative test for porphobilinogen, and it is so reported. If the color in the butyl alcohol layer is intense, indicating a heavy concentration of urobilinogen or other Ehrlich-reacting substances, extract the aqueous layer one or more additional times with butyl alcohol to be certain that none of the color in the aqueous layer is due to urobilinogen or other Ehrlich-reacting substances. If there is any doubt as to the identity of the pink or red color in the aqueous layer, it should be examined spectroscopically. Porphobilinogen shows 2 absorption bands, one at 560-570 mμ and a second weaker band at 515-530 mμ.
5. If the aqueous phase is positive for porphobilinogen, prepare a **reagent blank** as follows:
   (a) Measure 5 ml. of a saturated solution of sodium acetate into a No. 6-304 (19 × 150 mm.) Coleman cuvet.
   (b) Add 2.5 ml. Ehrlich reagent and mix.
   (c) Add 2.5 ml. urine. This urine is either undiluted or diluted, depending upon whether dilution was found necessary in step 2 above.
   (d) Add 5 ml. butyl alcohol to the contents. Shake and allow to separate into layers. If the separation on standing is not clear-cut, filter through a moistened coarse filter paper. The butyl alcohol layer comes to the top.
6. With the blank in the cuvet well of the spectrophotometer and at wave length of 565 mμ, set the galvanometer at 100% T.
7. Insert the cuvet containing the test solution and record the % T.
8. From the % T, read the porphobilinogen value (P) from Table 225 (prepared according to the Watson method, in which 2.06 mg. Pontacyl dye mixture is equivalent to 0.6 mg. urobilinogen). In this test, 1 mg. urobilinogen is arbitrarily equated to 1 unit porphobilinogen.

Calculation: Determine the total porphobilinogen content in the 24 hr. urine specimen by substituting the appropriate values in the following formula:

$$\text{Units of porphobilinogen/24 hr.} = P \times \frac{C}{A} \times \frac{V}{100} \times D$$

where

P = units of porphobilinogen in the unknown; obtained by reading the value from the urobilinogen calibration table corresponding to the % T.

C = total vol. diluted aqueous solution in the cuvet. This value is usually 10 ml. (2.5 ml. urine, 2.5 ml. Ehrlich reagent, and 5 ml. sodium acetate).

A = 2.5 ml. This represents the amount of diluted or undiluted urine used.

V = total vol. 24 hr. urine specimen in ml.

D = dilution factor if the urine was diluted. If the urine was not diluted, this value will be 1. If 1 ml. urine was diluted with 4 ml. water, for example, the dilution factor is 5.

Porphobilinogen is not detected in urine of healthy individuals by the methods now available. It is found in large amounts in acute intermittent porphyria (AIP) and to a lesser degree in mixed types of hepatic porphyria. It may be found in small quantities in urine of patients with lead poisoning and in some patients with chronic illnesses such as chronic leukemias and Hodgkin's disease but without symptoms of AIP. Since most patients with these conditions do not excrete porphobilinogen or increased amounts of uroporphyrins, it is believed that the exceptional patient in whom it does occur probably has latent porphyria.

Coproporphyrins and uroporphyrins—quantitative assay[42-52]

Principle: Coproporphyrins and uroporphyrins are usually found together in the urine. By acidifying the urine and adding ethyl acetate, the coproporphyrins are extracted with the ethyl acetate, from which they are later extracted by means of 1.5N HCl. The uroporphyrins remain in the aqueous phase and are concentrated by absorbing them onto an aluminum oxide column, from which they are eluted by 1.5N HCl. Since both coproporphyrins and uroporphyrins are fluorescent, their concentrations are measured by reading the fluorescence in a sensitive fluorimeter and comparing the intensity of each with that of a coproporphyrin standard in an identical vehicle. Since uroporphyrin is read against a coproporphyrin standard, a correction factor is necessary in the calculations.

In this procedure 5 ml. urine are used for both coproporphyrins and uroporphyrins. If greater sensitivity is desired when the uroporphyrins are in the normal range, 50 ml. urine may be used to obtain greater fluorescence of uroporphyrins. If 50 ml. are used, a correspondingly larger amount, 400-500 ml., of ethyl acetate must be employed.

Separation:

1. Into a 250 ml. Pyrex separatory funnel, measure the following:
   - (a) 20 ml. distilled water.
   - (b) 5 ml. well-mixed 24 hr. urine specimen.
   - (c) 100 ml. ethyl acetate.
   - (d) 5 ml. buffered acetic acid.
   - (e) 0.1 ml. 1% alcohol-iodine solution. The iodine converts porphyrin precursors to porphyrins.
2. Extract the coproporphyrins into ethyl acetate by shaking the contents of the separatory funnel 30 times, with periodic opening of the stopcock to allow gases to escape. Allow the contents to separate. The aqueous phase, containing the uroporphyrins, goes to the bottom and is drained into a 500 ml. graduate marked **uroporphyrins.** The ethyl acetate phase is retained in the separatory funnel.
3. Wash the ethyl acetate extract containing the coproporphyrins 3-4 times with 20 ml. portions 3% sodium acetate solution until the wash shows no blue-green fluorescence when checked in the photofluorometer. Make the zero setting with sodium acetate. (It is necessary to wash ethyl acetate thoroughly with sodium acetate so that the uroporphyrins which may have been carried over in small droplets of water into the ethyl acetate phase will be carried back into the aqueous portion.) At each washing shake 10 times and allow to separate. The aqueous layer goes to the bottom and is added to the 500 ml. graduate marked **uroporphyrins.**

Coproporphyrins—quantitative assay

1. Extract the coproporphyrins from the ethyl acetate phase in a separatory funnel 3 separate times, using 5 ml. portions 1.5N HCl (approximately 5%). Shake 30 times for each extraction. After each extraction, drain the lower aqueous layer into a graduated cylinder labeled **HCl extract.** Check the third HCl extract in the photofluorometer. Continue the extraction as long as there remains any characteristic orange-pink fluorescence in the last extract. Add all extracts to the HCl extract graduate and make up to a convenient vol. (usually 20-25 ml.), using 1.5N HCl.
2. The **concentration of coproporphyrins** is determined by means of a Coleman photofluorometer (model 12C) using a Coleman No. 12-224 filter as the primary filter. This filter is Corning filter No. 5113, which has its maximum transmission at 405 mμ and which cuts off below 350 mμ and above 480 mμ. A Coleman No. 14-220 red filter is used as the secondary filter. This filter transmits light only above 580 mμ, thus preventing the passage of the incident light and permitting the orange-pink fluorescent rays to pass. These filters are positioned in the photofluorometer. The sensitivity of this photofluorometer is increased up to 15-fold by connecting it to a Coleman spectrophotometer by means of a No. 12-057 connecting cable. Since only the galvanometer of the spectrophotometer is used, the passage of light rays through the spectrophotometer is prevented by turning a spectrophotometer cuvet adapter 90° either clockwise or counterclockwise in the cuvet well. The combination of the 2 instruments just described makes the Coleman photofluorometer a very sensitive instrument.
3. Turn on both instruments and allow them to warm for 10-15 min. The photofluorometer is turned on by means of the Standard control knob which should be turned to its full clockwise position. The neon bulb just above the knob glows when the current is on. Turn the coarse and fine Blank controls of the photofluorometer to full counterclockwise position. Set the aperture control to extreme right.
4. Turn the coarse galvanometer control of the spectrophotometer to the nearly full counter-

clockwise position and the fine galvanometer control to approximately midposition.

5. Place the blank, 1.5N HCl, in a No. 12-190 (105 × 19 mm.) cuvet in the cuvet well of the photofluorometer and cover. Adjust the galvanometer of the spectrophotometer to zero by means of the coarse and fine Blank controls of the photofluorometer. If the galvanometer index does not respond to the zero adjustment, the coarse and fine galvanometer controls of the spectrophotometer are probably at full counterclockwise position.
6. Place the 10 μg coproporphyrin standard in the cuvet well of the photofluorometer. Push the shutter button down, and adjust the aperture control until the photofluorometer meter reads 10. Recheck the zero setting with the blank and then reinsert the standard cuvet and set the galvanometer index of the spectrophotometer at 100 by means of the coarse and fine galvanometer controls of the spectrophotometer.
7. Recheck the zero and 100 settings until the galvanometer response is steady.
8. Insert the unknown solution into the cuvet well, push the shutter button down, and record the galvanometer reading. If the galvanometer reading goes above 100, dilute the unknown quantitatively as necessary, using 1.5N HCl until the galvanometer reading of the unknown is less than 100.

Calculations:

$$10 \times \frac{R}{100} \times \frac{V}{100} \times \frac{100}{A} \times \frac{24\text{ hr. vol.}}{100} \times D =$$

gamma (μg) coproporphyrins/24 hr.
where

10 = μg coproporphyrins used in the standard, equivalent to 10 gamma in 100 ml. 1.5N HCl, the fluorescence is directly proportional to the concentration.

R = reading of unknown.
V = final vol. to which the HCl extract is made.
A = vol. in ml. of urine excreted.
D = dilution factor, if it was found that the unknown had to be diluted to bring the galvanometer reading below 100. If no dilution was necessary, the value of D is 1.

Normal values:
Men: 100-300 μg/24 hr.
Women: 75-275 μg/24 hr.

With moderate to heavy consumption of alcohol these values may reach 350 μg/24 hr. Large quantities of coproporphyrin are excreted in both porphyria erythropoietica and hepatica. In coproporphyrinurias due to lead poisoning, infection, hepatitis, rheumatic fever, etc., there is a moderate to large increase in the 24 hr. output.

Uroporphyrins—quantitative assay

1. To the combined aqueous fractions in the 500 ml. graduate (from step 2 under "separation" described above) add an equal vol. acetone to make a 50% acetone-aqueous mixture.
2. Now set up an aluminum oxide slurry column in a chromatograph tube, as shown in Fig. 340.
   (a) Use chromatograph tube No. C-4080 (size 2, 19 × 200 mm.).
   (b) Introduce a plug of cotton at the upper end of the chromatograph tube. Dampen the cotton with 50% acetone and push it down the tube to plug the openings at the junction. If a chromatograph tube having a sintered glass filter at the bottom is used, the cotton plug may be omitted.
   (c) Make a slurry consisting of Al_2O_2 and 50% acetone containing 1% acetic acid and introduce it into the tube. Not all Al_2O_2 has been found to be satisfactory, and each lot must therefore be checked before it is used routinely.
   (d) Apply suction to the suction flask so that the slurry forms a column in the tube 5-7 cm. high.
   (e) To the top of the column add 2-3 mm. of sea sand which has been washed thoroughly with water and dried. The sand helps to keep the column intact.
3. Add slowly to the tube the 50% acetone solution containing the uroporphyrins and apply gentle suction. At no time during the process of adding the uroporphyrin-containing solution is the solution permitted to drop below the upper level of the slurry column although all the solution except a very small amount on the top of the slurry column is drained through. By means of an ultraviolet light source, it can be seen that the uroporphyrins will concentrate at the upper portion of the column as evidenced by the presence of a concentrated band of orange-pink fluorescence in this region. Wash the column 3 times with 1% acetic acid, each time nearly filling the

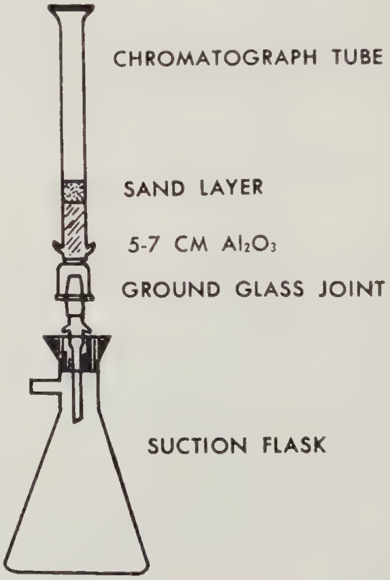

Fig. 340. Chromatographic column for uroporphyrin assay.

Method factor, 0.897.

chromatograph tube. Check the washings with an ultraviolet light for a blue-green fluorescence of urine and continue to wash until the washings are free of this fluorescence. Check the final washings with a photofluorometer. The washings will normally show the pink-purple fluorescence of acetic acid. Draw off the excess acetic acid in the slurry column with gentle suction, **discard the contents of the suction flask,** and reinsert the stem of the chromatograph tube into the suction flask.

4. Add 5 ml. 1.5N HCl solution to the chromatograph tube and apply gentle suction. By means of the ultraviolet light observe the uroporphyrins (orange-pink fluorescence) as they pass down the column. **Stop** the suction just before the uroporphyrins reach the bottom of the column.
5. Introduce a convenient-sized test tube into the suction flask and insert the stem of the chromatograph tube into the test tube. Add approximately 5 ml. 1.5N HCl to the chromatograph tube, apply suction, and collect all of the HCl extract into the test tube.
6. Remove the chromatograph tube and pour the contents of the collecting test tube into a graduate. Repeat step 5 until the washings no longer show a trace of orange-pink fluorescence when checked in the photofluorometer. All HCl extracts are added to the graduate. Make up to a convenient vol. with 1.5N HCl.
7. To measure the fluorescence intensity of the uroporphyrin extract the same combination of photofluorometer and spectrophotometer is used as described in discussion on coproporphyrins. Set the spectrophotometer galvanometer to zero on the black (lower) scale, using a 1.5N HCl blank and to 100 with a 10µg/100 ml. coproporphyrin standard. If the galvanometer reading goes above 100, dilute the unknown quantitatively as necessary, using 1.5N HCl until the galvanometer reading of the unknown is less than 100.

A coproporphyrin standard is used here because coproporphyrin is much more stable than is uroporphyrin. Since a coproporphyrin standard is used, however, the final results must be multiplied by 0.75, which is the factor required to convert the coproporphyrin reading to the uroporphyrin reading.

Calculations:

Micrograms of uroporphyrins excreted in 24 hr.

$$= 10 \times \frac{R}{100} \times \frac{V}{100} \times \frac{100}{A} \times \frac{24\text{ hr. urine vol.}}{100} \times 0.75 \times D$$

where

10 = coproporphyrin standard of 10 gamma/100 ml. 1.5N HCl.

R = reading of sample.

V = convenient vol. to which HCl extract was diluted in step 6.

A = vol. urine used. In most cases this will be 5 ml., but occasionally larger amounts will be used.

0.75 = transmission conversion factor to convert coproporphyrin reading to uroporphyrin reading

D = multiplication factor if a dilution was made in step 7.

Normal: 10-40 µg/24 hr.

WHITE BLOOD CELLS OR LEUKOCYTES

Although the level of erythrocytes is fairly constant in health, the level of leukocytes is subject to so many variations that it is difficult even to determine a normal level. The normal value is not influenced by sex or race.

The average total leukocyte count of the adult is 7400/c.mm. with a range of 4500-11,000/c.mm. Variations occur outside this range, an excess beyond 11,000 being called leukocytosis and a decrease below 4500 leukopenia. The average distribution is 40-75% granulocytes and 15-45% lymphocytes. Variations may occur in the blood of the same individual, even in health, from day to day or at different hours of the same day. Some authorities have spoken of digestive leukocytosis, supposedly associated with food intake. There is some question as to whether there is justification for such a designation since variations may occur quite independently of meals.

Medlar[53] investigated the differences between leukocyte counts in individuals at rest and after exercise and found that there is no such thing as an absolutely constant leukocyte level and that fluctuations in the leukocyte picture are very inconsistent. A fluctuation of more than 50% of the total count and of over 8% in the differential count must occur before much significance can be placed on the changes in these values.

Apart from the diurnal variation, there are variations as a result of age. At birth, the leukocyte count averages 18,100/c.mm., with a range of 9000-30,000. At the end of 1 week, there is a drop in the total leukocyte count to an average of 12,200, with a range of 5000-21,000. These levels tend to persist until the end of the first or second year and then continue to fall within the normal average. Until the age of 4 to 5 yr. has been reached, there is a tendency toward the slightly higher leukocyte counts within the normal adult range.

The leukocytosis of the first few days of life is mainly due to polymorphonuclear cells which then begin to fall, whereas the lymphocytes begin to increase. At the age of 4 to 5 yr. the lymphocytes begin to fall again, and the granulocytes increase.

The white count does not seem to be affected appreciably by altitude.

During pregnancy, there is usually an elevated count of approximately 10,000-10,600, or even as high as 15,000. By the fifth to ninth week post partum, there is a return of the total leukocyte count to within the normal average and normal range.

Physical exertion produces leukocytosis. Stress and emotional distress of long duration are followed by an elevation of leukocytes and an increase in lymphocytes.

FATE AND PHYSIOLOGY OF WHITE BLOOD CELLS

At this time neither the duration of life nor the mode of destruction of the white cells is definitely known. It is generally believed that disintegration of leukocytes in the blood stream does occur. It is probable that white cells are consumed in greater amounts than the red cells. Since there are only $\frac{1}{1000}$ as many white cells in the peripheral blood as red cells, the time of their development must be longer or their life must be much shorter. There must be, according to the present figures, at least an age of 2 hr. for a leukocyte. Ponder, on the basis of Arneth's shift to the left, attempted to calculate the life of leukocytes and found it to be from 2-3 weeks. The segmentation of white cells according to Schilling[54] is not a measure of their age. Magner[55] states that the life of the leukocytes is probably not longer than a few days, but that some workers believe that the nonmotile cells which are seen in supravitally stained preparations are artifacts. Many leukocytes penetrate the capillary walls, wander through the tissues, or escape from the body through mucous surfaces. By virtue of their phagocytic powers and by the production of bacteriolytic substances, they are active in the defense of the body against pyogenic bacteria, and they also play an important part in the digestion of necrotic tissues by means of proteolytic enzymes.

Leukocytic life is rhythmically regulated. The contribution of Sabin et al.[56] covers the question of the normal rhythm of the white blood cells. This contribution has given us a better understanding of the physiology of the white blood cells. The study was worked out through supravital technic. As described by Sabin,[57] a type of cell exists in the blood which she called the nonmotile leukocyte. This loss of movement is essentially a chemical and physical change in the neutrophilic granules, together with a loss of power to react to vital stains. This cell was first described by Schilling[58] in 1908. He noted the cessation of motility and also described the subsequent disappearance of the centrosphere. He maintained at that time that it represented the physiologic death of the leukocyte. Cunningham, Sabin, and Doan noted the showerlike appearance of these dying cells in the blood. They believed that if one could arrive at an estimate of the amount of cell death of the leukocytes in the blood stream one might devise some method of analyzing the rhythm of the leukocytes. Counts of the white cells of human subjects at different times of the day had previously been made. Torday[59] found the lowest count in 61 patients was 3130 and the highest 9800. Turk[60] found the normal count at different times of day was from 5000-10,000 white cells. Most of the studies on the rise and fall of leuko-

Table 226. *Staining characteristics (Wright-Giemsa) of cells of granulocytic series*

Nucleus	*Cytoplasm*
Myeloblast (Naegeli): round, finely reticular in structure, with blue plastin nucleoli	Highly basophilic, no granules; faint to strongly positive oxydase reaction
Promyelocyte (Pappenheim): round, with a tendency to polymorphism and lobulation, especially true under pathologic conditions; plastin nucleoli at times faint or completely absent; whole structure denser and darker	Dark blue to pale blue; beginning deep red azurophilic finer or coarser granules (progranules)
Myelocyte (Ehrlich): round, oval, to slightly indented, only chromatic nucleoli; coarser and darker interstices	Pale blue to neutral, mature neutrophilic, basophilic, or eosinophilic granules
Juvenile granulocyte (Schilling): sausage-shaped, well-filled structure distinctly divided into fields, frequently with polar nucleoli	Occasionally slightly basophilic, usually neutrophilic granules very intensely stained, with a tendency to azurophilic characteristics
Stab or *rod nuclear granulocyte* (Schilling): slender, darker, often with a twisted nucleus with bizarre indentations suggestive of beginning segmentation	Mature granules
Segmented granulocyte (Schilling): nucleus with many divisions; 2-5 segments connected in a chain by fine threads or bridges	Mature granules

cytes have been made in pathologic conditions.

Investigators have found that the injection of foreign proteins, bacteria, drugs, etc., produces very definite leukopenia followed by leukocytosis. It has been found by some observers that variations in the blood pressure are followed by changes in the number of blood cells, a lowering in the pressure being followed by a decrease in the number of cells. Arneth[61] and other investigators have found that there is a definite increase in the number of white blood cells after a cold bath. Change in posture has been followed by variation in the number of leukocytes. It was also found that muscular work caused a constant increase of leukocytes and that this disappeared in the course of 2-3 min. but reappeared again on renewed exercise.

Digestive leukocytosis has been studied by a number of investigators. Pohl[62] studied digestive leukocytosis in dogs after 18 hr. of fasting and found after feeding them meat that they had leukocytosis beginning in 1 hr. and reaching a maximum at 3 hr. With nonalbuminous foods he obtained no leukocytosis. Rieder[63] confirmed Pohl's findings both in man and in dogs. Sirensklj,[64] in studies on man, found digestive leukocytosis after meals rich in albumin or in fat but only a very slight reaction after food consisting of carbohydrates alone. Pirone[65] from histologic studies of the blood-forming organs during digestion concluded that the reaction had 3 phases: (1) increased destruction of the older blood cells, (2) increased stimulation to the formation of new cells and the migration of elements into the blood stream, and (3) signs of hyperfunction and increased hematopoietic activity in the bone marrow, spleen, and lymph glands. The work of Cunningham and associates has given the best information on the question of the rhythm of white cells. It is fairly constant for 7-8 hr. as shown by supravital preparations. They showed that the white blood counts are higher in the afternoon than in the morning quite independently of whether food is taken.

Physiology of polymorphonuclear leukocytes

The physiology of the formation of granulocytes has been thoroughly studied. We know that granulocytes, like erythroblasts, are formed in well-defined centers and that promyelocytes and myelocytes, characterized by blue cytoplasm and light, nucleolated nuclei, develop from these centers. In the bone marrow before this stage has arrived in the maturation of granulocytes, there can be seen large basophilic cells with nucleolated nuclei, the so-called Pappenheim's lymphoidocytes, Maximow's polyblasts or primitive cells, Ferrata's hemocytoblasts, or Schilling's undifferentiated parent cells. Schilling[54] illustrates the various stages through which the granulocyte passes before it becomes a fully mature segmented granulocyte.*

---

*See Table 46 in Schilling, V.: Handbuch der normalen und pathologischen Physiologie, part 2, Berlin, 1928, Julius Springer, p. 789.

In this connection attention must be called to the differences between the Arneth and Schilling theories of shifts in blood pictures, which is discussed under remarks on differential counts.

The physiologic importance of the segmented forms lies in their phagocytic activity, their enzyme production, and their ameboid motility.

Basophilic granulocytes: Basophilic granulocytes are the blood mast cells and are related to the tissue mast cells which are occasionally encountered in bone marrow smears. These cells produce and store heparin and are related to the production of hyaluronic acid and serotonin. See discussion of mast cells.

Eosinophilic granulocytes: Barnhart and Riddle,[66] in Seeger's coagulation laboratory, have shown by immunologic methods that eosinophils are the only cellular source of plasminogen (prefibrinolysin). Eosinophils are commonly seen in immune or allergic reactions and are dependent on hormonal activity.

Physiology of lymphocytes[67-73]

According to Sabin,[67] lymph sacs are formed in the embryo of 6-24 mm. near the jugular vein. These sacs become the so-called lymph hearts. The latter form the primary lymph glands (embryo from 10.5-30 mm.). The first lymph follicles appear in the embryo of 50 mm. Lymphocytic cells develop from the mesenchymatous migratory cells of the adventitia of blood vessels in the tissues between the lymphatic capillaries. Maximow[68, 70] designated the first free mesenchymatous migratory cells as lymphocytes. He insisted that from the primitive cells true small lymphocytes may form and that even the lymphocyte of the blood preserves this polyblastic embryonal capacity. There is good evidence that in a 4 mo. fetus the lymphocytes originate in the thymus. Later they are produced in the spleen and lymph nodes. The first circulating lymphocytes are of the large type, whereas in the second half of gestation the small lymphocytes take over and form the majority of the circulating white cells.

The follicle is the unit of true lymphatic tissue. Lymphatic tissue is found extensively all over the body. The lymph nodes and spleen furnish the true lymphocytes to the blood stream. The follicle has a germinating center. This consists of lighter and larger cells with vesicular nuclei and distinct nucleoli.

Flemming believed that the formation of lymphocytes emanates from the cells of the germinating centers. Naegeli and Schridde call these cells lymphoblasts. These lymphoblasts are offspring of reticulum cells and give rise to large lymphocytes which in turn change to small lymphocytes. This transition from large lymphocytes to small ones has been proved by incorporating radioactive tritium-labeled thymidine into the deoxyribonucleic acid of the cells in the stage of DNA synthesis (mitosis). The life span of lymphocytes labeled with P^{32} or chromium^{59} is about 100 days. They circulate from the blood to the lymph nodes and return by means of the efferent lymphatics and the thoracic duct. Lymphocytes are destroyed in all the organs in which they are formed (liver, spleen, thymus, intestines, lung, and lymph nodes). The production of lymphocytes is influenced by adrenal cortical extract which, when administered in excess, diminishes the circulating lymphocytes to 50% or more of the original level.

The lymphocyte is probably not a homogenous cell type. In certain conditions lymphocytes can give rise to plasma cells, as seen in macroglobulinemia, in which one observes transitional stages between lymphocytes and plasma cells in the bone marrow. By electron microscopy, lymphocytes never show an ergastoplasm, which is characteristic for the globulin-producing plasma cells. In this connection the condition of alymphocytosis described by Hitzig[73] is of importance since it is characterized by absence of lymphocytes, plasma cells, and gamma globulin. The protective effect of administration of splenic emulsion or of shielding the spleen during total body irradiation in experimental animals has brought up the problem of conversion of lymphocytes to pluripotential reticulum cells from which marrow regeneration can occur. The pathology and the interrelationship of the various types of lymphomata also suggests such a conversion possibility.

Schilling observed true lymphocytic cells in bone marrow, especially in chronic conditions. They may form lymph follicles. There is no evidence that their presence foreshadows the future development of one form or another of lymphoma.

We know that in the adult about one fourth of the circulating white cells are lymphocytes, but they are only a small part of the total number manufactured. Young immature lymphocytes, not blast cells, may occur in the peripheral blood in apparently normal persons and occur frequently in lymphocytic leukemoid reactions, such as virus diseases, hepatitis, and infectious mononucleosis (virocytes). In contradistinction to the young lymphocytes, the more mature lymphocytes are present in the intestinal tract and lymphatic system rather than in the blood stream.

The **function of lymphocytes** is recognized in the walling off of chronic inflammatory foci. They are increased in chronic inflammatory states. They are increased also during infancy and in recovery from acute infections and in certain diseases such as measles, mumps, whooping cough, and undulant fever.

Lymphocytes are slowly moving cells which under certain circumstances show phagocytic activity and are able to leave the confines of the blood vessels to become tissue cells. They may transform into large ameboid macrophages. Some lymphocytes appear to be responsible for antibody formation and may during antibody synthesis transform into plasma cells. One of the most interesting aspects is their relationship to the delayed type of allergy of skin reactions (e.g., tuberculin test). Apparently this response is linked to the lymphocyte and is transferable from patient to patient by lymphocytes. It is independent of serum globulin levels or of other humeral factors.

Physiology of monocytes

Ehrlich called all cells with eccentric pale nuclei and large faintly basophilic cytoplasm, generally without granulations, large mononuclear cells. He differentiated these from transitional cells which had deeply indented nuclei, constituting the beginning of neutrophilic granulations. He believed that these cells were transitions to neutrophils. Pappenheim claimed that they were older lymphatic forms of the Rieder type. All authors except Pappenheim traced these cells to the neutrophilic system. Einhorn and Ehrlich believed that a relationship existed between these cells and the spleen and called them splenocytes. Pappenheim and Ferrata in 1910 finally suggested the name monocytes for both the mononuclear and transitional cells. Pappenheim[74] was the first to identify the monocytic granules as **not** neutrophilic and **not** true granules, and Naegeli admitted in the same year that the granules were azurophilic and not neutrophilic. Schilling emphasized that the oxydase reaction indicates that the monocytes occupy something like an intermediate position between the other systems. He demonstrated basophilic juvenile forms in variola and also the close relationship between the blood monocytes and endocarditis lenta. He concluded that the peripheral macrophage is merely a functional form, coming from the same parent cells as the monocytes, and that the monocytes could be converted into macrophages.

Schilling sought to find the genesis of monocytes in the reticuloendothelium structure, that is, the endothelium of hematopoietic organs and the Kupffer cells of the liver. Maximow opposed this view with his histiocytic or lymphocytic origin of monocytes. He explained the monocytes as physiologic blood polyblasts.

The functions of monocytes are phagocytosis and storage. Phagocytosis is least developed in the bone marrow monocyte and best developed in the tissue monocyte. The latter may be stationary or mobile. They respond to adrenal cortical extract in the same way as lymphocytes; they decrease 50% or more.

Plasma cells

Plasma cells are closely related to lymphocytes and reticulum cells. In macroglobulinemia, various transitional forms can be seen which have been named lymphoid reticulum cells and lymphoid plasma cells or lymphocytoid cells. The normal bone marrow plasma cell produces gamma and beta globulins or is at least responsible for their release. Under pathologic conditions, the plasma cell is responsible for the modification of plasma proteins and the production of paraproteins, macroproteins, and various abnormal protein states (dysproteinemias), e.g., cryoglobulins. As antibodies consist mainly of gamma globulins (but not all gamma globulins take part in the antibody formation), the plasma cells are closely related to the resistance of the organism. The rare plasma cell appearing in peripheral blood is not involved in protein production. Various morphologic findings such as intercytoplasmic Russell bodies and crystalline inclusions, as well as clinicopathologic findings, speak for the role of the plasma cell in protein synthesis. In pathologic conditions associated with hypergammaglobulinemia there is usually an increase in bone marrow plasma cells. Hypergammaglobulinemia or hyperbetaglobulinemia is usually associated with multiple myeloma. The role of the plasma cell in protein metabolism is challenged by such conditions as mutliple myeloma without hypergammaglobulinemia and macroglobulinemia and amyloidosis without an increase in plasma cells. In agammaglobulinemia and hypogammaglobulinemia there may be lymphoid hypoplasia or hyperplasia, but there is usually a disturbance in production of plasma cells and thus a diminution in bone marrow plasma cells. The ergastoplasm within the cytoplasm is responsible for the protein production, as shown by electron microscopy.

BLOOD PLATELETS

Blood platelets appear in the stained specimen as single, bright, azure, rounded, or elongated small bodies with a delicately striped and granular structure. They are about ½ to ⅕ the size of red cells.

The past dispute as to the source of blood platelets is of historic interest only. Bessis has shown in beautiful phase contrast pictures the formation of platelets within the megakaryocytes and their release into the bone marrow. Kinosita in a motion picture showed the production of platelets by megakaryocytes observed through windows in rabbit bones. Vazquez by means of fluorescent antihuman platelet serum proved the presence of at least one common antigen in platelets and megakaryocytes. Earlier histochemical studies of acetylcholinesterase led to similar conclusions.

Each platelet consists of a central body, a granulomere, and a surrounding hyalomere which forms pseudopodia.

Chemically the platelets are rich in adenosine triphosphate (ATP) and glycolytic enzymes. The ATP content is apparently related to clot retraction. Platelet phospholipids (phosphatidylserine) increase blood coagulability in vitro. Phosphatidyl ethanolamine is active in the coagulation mechanism only when combined with lecithin. As already stated, in the embryo platelets make their appearance at the same time as megakaryocytes can be found. The platelets are produced by the megakaryocytes in bone marrow. Megakaryocytes are also found in the lung and spleen but are apparently not platelet-producing in these tissues. Platelets survive 3-6 days in the peripheral circulation and are then destroyed in the spleen.

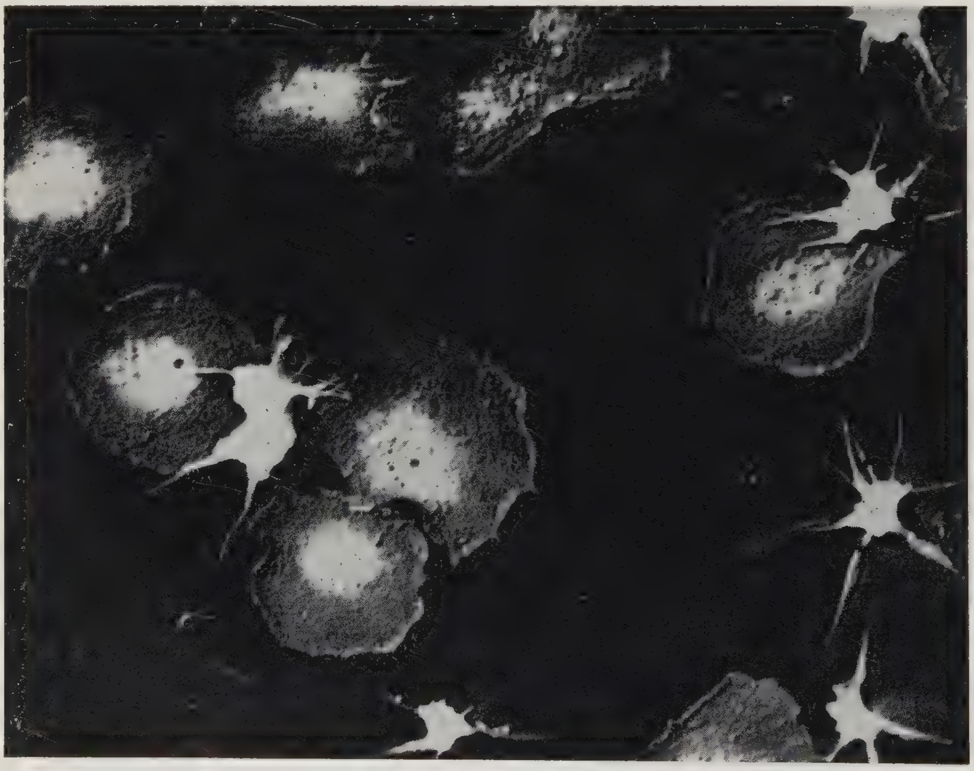

Fig. 341. Normal platelets with pseudopods and spreading of hyaloplasm. Electron micrograph. (Courtesy Prof. H. Braunsteiner, Vienna, Austria.)

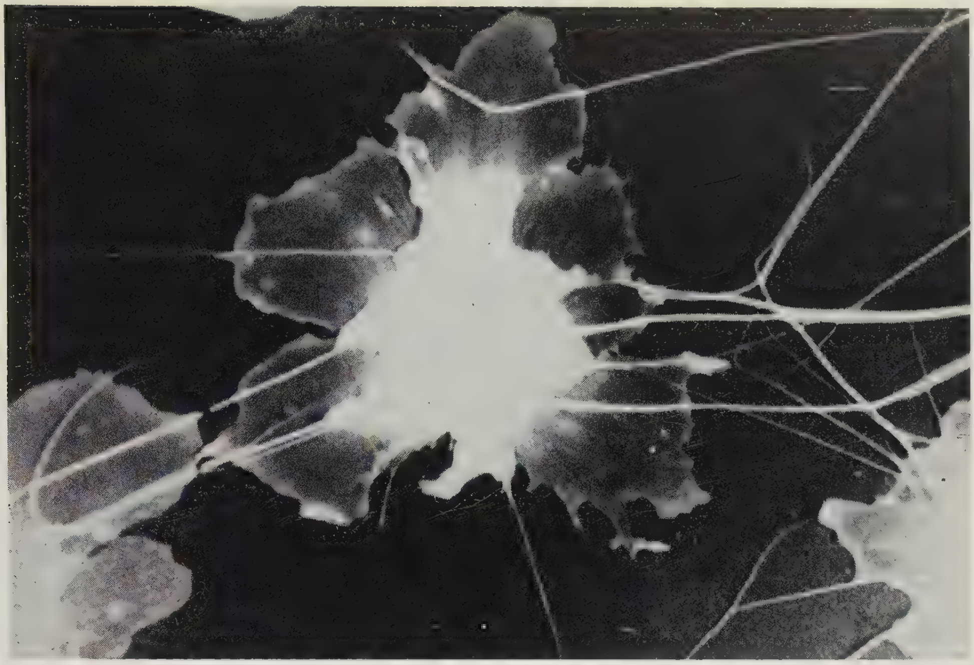

Fig. 342. Platelets in early stages of coagulation, showing viscous metamorphosis. (Courtesy Prof. H. Braunsteiner, Vienna, Austria.)

The total number of circulating platelets is fairly constant in health and is not subject to great variations. In normal plasma there exists a thrombopoietic principle which stimulates megakaryocytic maturation and platelet production.[75]

Functions of platelets[77, 78]

The functions of platelets are concerned with hemostasis and blood coagulation and can be broken down into several phases which in vivo may well occur at the same time.

Initiation of blood coagulation: By means of their adhesiveness, platelets adhere to the injured intima of the blood vessel and release platelet factors which lead to platelet agglutination and formation of platelet plugs. Electrostatic forces have been suggested as the basic mechanism of platelet adhesiveness. On the other hand, deposition of minimal amounts of fibrin may be the initial mechanism.

Vasoconstriction: When platelets disintegrate, they release 5-hydroxytryptamine, a substance which is formed in the gastrointestinal tract by argentophil cells and is transported and concentrated by the platelets; 5-hydroxytryptamine is called **serotonin,** and probably in unison with a second platelet factor it acts on the arterioles, leading to narrowing of the lumina. Thrombin may be required for the release of 5-hydroxytryptamine which interacts with a plasma factor. The metabolism of serotonin results in the production of 5-hydroxyindoleacetic acid which is excreted in the urine and can be detected by appropriate tests.

Platelet agglutination: The agglutination of platelets concerned with hemostasis differs from the immunohematologic platelet agglutination. Normal platelet agglutination can be produced by many substances such as peptone, heavy metals, plasma, serum, saponin, etc. Heparin prevents platelet agglutination.

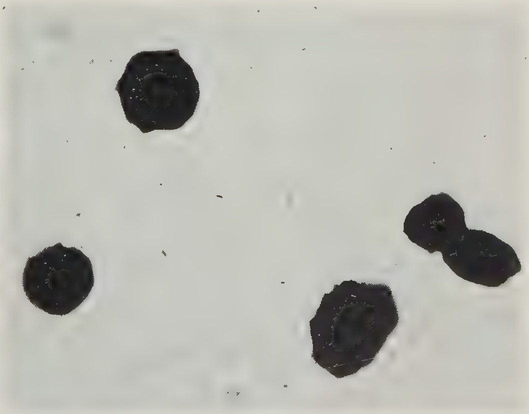

Fig. 343. Platelets in thrombocytasthenia. Defective pseudopod formation and lack of spreading. (Courtesy Prof. H. Braunsteiner, Vienna, Austria.)

Immune agglutination is considered in the discussion of immune thrombocytopenia.

Platelet groups and types: Platelets belong to the A-B-O system and to several subgroups. This aspect is considered in the discussion of immune thrombocytopenia.

Platelet factors: According to Seeger,[76] platelets contain 11 factors such as prothrombin activator, thrombin activator, accelerator globulin-like factor, antiheparin factor, etc.

Clot retraction: Clot retraction is a characteristic function of platelets producing contraction of the fibrin network of the fresh clot. Viscous metamorphosis of the platelets precedes their action on the fibrin network. Clot retraction parallels platelet adhesiveness and aggregation, as well as being related to the number of platelets. Viscous metamorphosis of the platelets first leads to platelet aggregation, then to platelet fusion, and finally to release of platelet factors. Some of these aspects are considered again in the discussion of coagulation.

Physiologic variations of the platelet count

Normal values (indirect method): Normal values for the indirect method are 250,000-400,000/c.mm. blood. Various counting methods give different normal values for platelets. The indirect method, which determines the number of platelets per 1000 red blood cells, is influenced by the distribution of platelets on the slide, whereas the direct method of counting platelets is influenced by the breakdown of platelets in the counting fluid.

Variations in the number of platelets occur from individual to individual but are only slight in a given individual during each 24 hr. period. An increase in the number of platelets is noted from birth to the age of 3-12 mo., after which normal values are obtained.

The behavior of platelets in conditions accompanied by or leading to venous thrombosis has been extensively studied. Two such conditions are pregnancy and surgical operation. During pregnancy the platelets are normal, but after delivery their number increases for about 7-10 days. Similar platelet increases may be seen following surgical operation. Splenectomy is characteristically followed by a temporary (seldom permanent) increase in platelets so that some splenic controlling mechanism can be postulated.

Chapter 61

Technics in hematology

JOHN D. BAUER

INTRODUCTION

Blood examinations are important in completing the examination of every patient. These tests must be performed with consummate technical skill, utilizing procedures and equipment best suited for various situations. Certain hematologic tests can be considered as basic routine "screening" procedures. These should include hematocrit and hemoglobin determinations and a white blood cell count, with examination of a properly prepared blood spread. The results of these tests will often point the way to other special procedures, or the history and physical examination may indicate the need for more exhaustive hematologic investigation of the patient. In the ordering of tests or the interpreting of results, knowledge of the normal ranges, rather than some fixed number, and of the limitations of accuracy of the procedures are of inestimable value to the physician.

Sound planning in the laboratory implies a thorough knowledge of equipment and procedures which can be gained only by consistently keeping abreast of such matters by reading the literature and by attendance at meetings especially aimed in these directions. The purchase of equipment should be based on the work to be done, as well as on the accuracy of the instrument. For example, photoelectric hemoglobin methods lend themselves readily to assembly line organization, which makes them a real economy in technician time. At the same time, maximum accuracy can be obtained by use of a photometer. In a laboratory doing a large volume of work, such equipment becomes almost a necessity. However, the less expensive visual hemoglobinometer may serve satisfactorily in a physician's private office if the volume of work is minimal. In either case, knowledge of the limitations of the equipment is necessary for proper appreciation of the results. An improperly standardized expensive photoelectric apparatus may be more inaccurate than less expensive equipment. In both instances, careless technic will militate against accuracy.

The choice of procedures and full knowledge of their limitations should be considered. Frequently, relatively simple procedures will suffice and thus eliminate more complicated and more time-consuming technics. The estimation of blood platelets is a good example of such a situation. In a properly prepared blood spread, if platelets are seen in every oil immersion field, it can be safely said that thrombocytopenia does not exist. In clinical conditions with bleeding diathesis and obvious normal numbers of platelets in the spreads, the actual counting of platelets is unnecessarily time-consuming. On the other hand, if trends in numbers of platelets are to be determined, then platelet counts by more precise methods are in order. There may be situations in which simple or commonly performed tests may not reveal any abnormality and it might be necessary to perform some little known or infrequently used test to uncover the basic disorder. An example of such is the plasma thromboplastin component (factor IX) determination in a patient with a bleeding diathesis with normal routine test results.

These are but a few examples of intelligent choice of procedure indicated by the clinical state of the patient. The choice of technic may be influenced by the range of accuracy desired or desirable. Erythrocyte counting, for example, lends itself to scrutiny from this standpoint. The primary purpose of a red blood cell count is determination of the presence or absence of anemia or polycythemia. In routine work, significant deviations can be determined simply with an accuracy of ±5% for hemoglobin and ±2% for hematocrit. On the other hand, routine erythrocyte counts using 1 pipet, 1 chamber, and 500 red blood cells are subject to an inherent error of ±16%.[79, 80] This means that a red blood count that is actually 5,000,000/c.mm. may be reported as 4,200,000 or 5,800,000/c.mm. at either extreme. These discrepancies in the limits of accuracy of this test should make it quite obvious as to the choice of tests for routine work, namely, the elimination of the red blood count. If the hematocrit and hemoglobin tests reveal subnormal values, then a well-made erythrocyte count is indicated. We heartily endorse Ham's[80] recommendation as to the minimum procedures for red blood cell counting for clinical use: 1 pipet, 2 chambers in the hemacytometer, and counting 400-600 cells per chamber. For determination of the corpuscular constants (mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration), Ham recommends using 2 pipets and 2 chambers and counting 400-600 red cells in each chamber.

It is of utmost importance that technicians present an appearance to the patient and to the physician that reflects confidence. Laboratory technicians should appear neat and clean; particularly is this true of the hands. Constant observation, reading, and the repeated performance of tests will aid in bestowing confidence in oneself, which will be reflected in the patient's response. It is important for technicians to become thoroughly familiar with all phases of every test that they perform and to know the limitations of the particular test that they are reporting. There is too great a tendency for some persons to believe that results obtained in many tests are rigidly accurate scientific figures. For this reason, in the following section on technic and in some of the preceding sections, a mean average and a range of the test are included. The standard values that follow have largely been taken from *The handbook of biological data.*[81] This compendium of data was obtained by contributions "by experts in the various areas of hematology. These tables have been reviewed by outstanding specialists in the subjects covered and represent an unusually complete collection of data on blood, which is unique in the high degree of reliability. Over 600 leading investigators in biology and clinical science were consulted for the accumulation of these data. In addition, numerous outstanding experts reviewed the material prior to publication for its accuracy."*

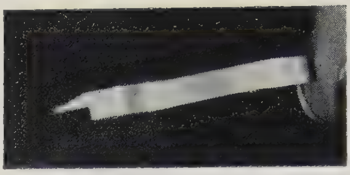

Fig. 344. Hemolet. (Courtesy Scientific Products Division, American Hospital Supply Corp., Evanston, Ill.)

The one procedure common to all hematologic tests is the drawing of blood samples from patients. This procedure must at all times be carried out with full knowledge and appreciation of asepsis. **All materials which touch the patient for obtaining a blood specimen must be sterile.** This means sterile needles, cotton, and syringes. The skin must be thoroughly cleansed with some antiseptic—alcohol, alcohol-ether mixture, acetone, Merthiolate, Zephiran, or other preparations. After a skin area has been cleansed, the operator must not touch the area with the fingers. It is too common a practice to locate a vein in an arm, cleanse the area, and then proceed to palpate the area again with the nonsterilized finger before inserting the needle. **It must be repeated that if the finger touches the area to be punctured, this area must be cleansed again.**

Instruments used to puncture the skin: Any instrument used to puncture the patient's skin for the purpose of obtaining blood for examination must be absolutely sterile. **This does not mean that one may use a needle attached to a cork which is carried point downward into a small bottle containing alcohol or any other chemical or disinfecting liquid.** Sterility means just what it implies, namely, actual killing of bacteria or viruses. It is well known that cases of infectious hepatitis, for instance, have occurred in hospitals when imperfectly sterilized needles and lancets have been used.

Four different methods are suggested. (1) Break sharp-pointed pens in half, wrap a number in paper, and sterilize by dry heat at

170° C. for 1½-2 hr. (2) Use Hemolets* (Fig. 344). Hemolets are razor-sharp ribbons of stainless steel packaged in sterile wrappers. They are thrown away after being used once. (3) Use Sera-Sharp† sterile disposable lancets (Fig. 345). These also are used once and discarded. They are inexpensive and need not be used more than once. When Hemolets or Sera-Sharp lancets are used, the possibility of transmitting infectious diseases such as virus hepatitis, homologous serum jaundice, malaria, etc. through skin puncture can be precluded. Both the Hemolet and the Sera-Sharp make the puncture about the correct depth, not too shallow and not too deep. (4) Use the Steri-Lance† (Fig. 346).

To use the Steri-Lance, place all lancet heads into the side of the container marked Sterile. Place the lancet holder in the center groove. Sterilize the complete unit at 15 lb. pressure for 30 min., in an autoclave.

To attach the blade unit, slip the end of the holder over a sterile lancet head and screw on securely with a few turns of the holder. Holding the assembled lancet with the blade up, turn the screw cap of the opposite end until the tip of the blade is just barely visible. Once adjusted, the holder will give a uniform depth of penetration with all blades. The lancet blade is not attached to the spring but has a special recoil action. Pull out the top cap of the holder until the spring catches, place the tip of the lancet blade against the disinfected skin in the usual manner, and press the release level.

After use, wipe the blade clean, then place the lancet head in a pocket on the unmarked side of the insert, and unscrew by twisting the handle. **It is never necessary to touch the lancet blade or head at any time.** After all the blade units have been used, the complete unit is ready for sterilization. To prevent confusion, do not transfer blade units from unsterile to sterile side until they are ready for sterilization.

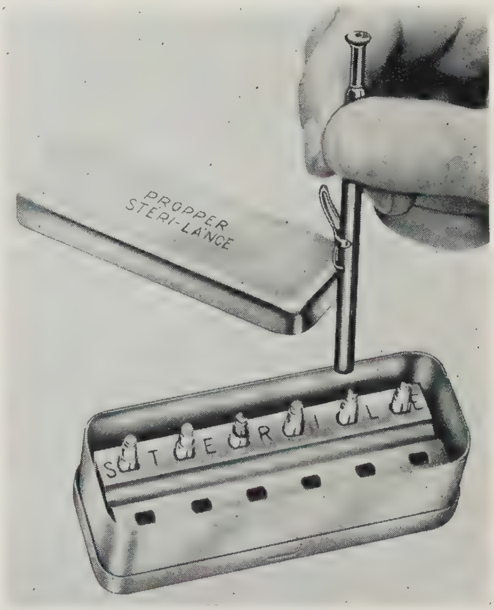

Fig. 346. Steri-Lance, an adjustable automatic lancet for skin puncture. (Courtesy Propper Manufacturing Co., Inc., Long Island City, N. Y.)

Technic of puncture:

1. To use the sterile pen point, Hemolet, Sera-Sharp, or Steri-Lance, hold the lobe of the ear between the thumb and forefinger.
2. Place the puncture point on the lobe of the ear and make a quick incision. If the hand is used, hold the hand tight before making a jabbing puncture. Blood should ooze in small drops spontaneously or with very slight pressure. **Do not use strong pressure to increase bleeding.** Such pressure causes the blood films to become contaminated with tissue juice and endothelial elements and alters the patient's counts.
3. Remove the first small drop of blood and then proceed with the various counts and blood spreads. When finished, wipe the skin with alcohol and discard the used cotton.

Proper types of blood samples are important; their source is often dependent upon the nature of the test to be performed. Some routine hematologic procedures such as red blood count, white blood count, hemoglobin, and blood spread can be obtained from capillary blood taken by simple skin puncture, as directed above.

†Propper Manufacturing Co., Inc., Long Island City, N. Y.

Blood specimens for many hematologic procedures are obtained in many hospitals by venipuncture.

To use venous blood: The method of making a venipuncture in an adult is given on p. 29.

Venous blood must be transferred quickly to a suitable anticoagulant to prevent clotting. A satisfactory anticoagulant mixture known as **3:2 oxalate mixture** is prepared as follows:

Ammonium oxalate . . .	1.2 gm.
Potassium oxalate	0.8 gm.
Distilled water	100 ml.

1. Use 0.1 ml. for each ml. blood after the anticoagulant has been dried. For routine work requiring 5 ml. blood, place 0.5 ml. into test tubes or suitable wide-mouthed bottles.
2. Allow to dry or heat gently in an oven to evaporate the water, which leaves a white dry powder on the bottom of the collecting vessels. Stopper and keep away from dust.
3. Place the blood into the anticoagulant tube and invert gently 5-10 or 20 times to ensure adequate mixing of the anticoagulant and blood.

Venipuncture in infants: To obtain a large sample of venous blood from an infant one may perform a femoral or jugular vein puncture. Both procedures are relatively formidable and should be undertaken only by a physician and not by a technician.

For small quantities of blood one can easily obtain samples by puncture of the baby's thumb, large toe, or heel. This should be done under strict asepsis, namely, cleansing of the skin and of the puncture points with an antiseptic soap and water or by saline solution and then using one of the skin antiseptics, such as a 1:1000 solution of tincture of Merthiolate. After this is applied and allowed to dry, punctures are made with an extremely sharp-pointed surgical knife. One with a long, tapered point is preferred (Bard-Parker blade No. 11). When several of these punctures are made, with constricture of the ankle, enough blood can be obtained to carry out a serologic procedure and chemistry determinations if the heel or toe is used.

Blood kept in the anticoagulant may be used for making erythrocyte counts, hemoglobin determinations, white blood counts, sedimentation rates, hematocrit determinations, fragility tests, reticulocyte counts, icterus index, and other tests, if performed within 3-4 hr. after collection of the blood sample.

Blood taken in an anticoagulant is generally unsatisfactory for the preparation of blood films because both the leukocytes and the red blood cells show morphologic alterations that render cell identification difficult at times. With a little practice, it is possible to take a small drop of blood from the needle at the time of venipuncture, place it on a glass slide, and make a satisfactory blood spread.

Precautions to be observed in handling blood for hematologic study: The blood sample should be kept away from excessive heat, such as a radiator under a laboratory table or an oven, since heat will hemolyze the blood.

Thorough mixing of the blood specimen prior to removal of samples for each examination is necessary to secure true sampling of the specimen.

One advantage of collecting blood routinely in an anticoagulant is that tests may be repeated and extra procedures can be carried out if indicated without recalling the patient and repeating the venipuncture. Another advantage is the multiple number of tests which may be performed without concern about clotting of blood before pipetting has been done or closing of the puncture wound before sufficient specimen has been collected.

Glassware must be thoroughly cleaned and dried. Immediately after they are used, the pipets, counting chambers, hematocrit tubes, etc., must be cleansed with cold water to prevent the glassware from being stained with dried blood. If these instruments become brown, they must be treated with strong acids or ammonium hydroxide, which is undesirable.

Slides and cover slips used for preparing blood spreads must be new and not reused, and they should be cleaned thoroughly. Ordinary glass slides may be cleaned readily by the vigorous use of clean dry gauze. The fingers must not touch the edges of the slide nor the slide surfaces.

The care and use of the microscope are discussed in Chapter 1. For oil immersion work, maximum light intensity with the condenser in the closest position to the blood film and the light shutter open to its maximum will give the clearest picture of the fields.

Reporting results of laboratory tests is an important function of the laboratory. Even the most meticulous technic requiring many hours of time would be worthless if the results were not recorded in some proper manner. Reports should display normal values and ranges for normal values, as well as the result of a particular test. Duplicates of reports should be retained by the laboratory for future reference. Promptness in reporting will gain the plaudits of the referring physician. Reports on examination of blood films should be so worded that the referring physician can visualize the film. Laboratory reports constitute one link in the chain of confidential relationship between patient and physician. Laboratory technicians have been taken into this confidence. **Under no circumstances should they betray this confidence by revealing reports to persons unauthorized to receive such information.**

All material, such as blood specimens and reagents, must be properly labeled in order to avoid both confusion and error. Labeling of blood should be performed at the time the material is collected. Bottles or test tubes may be labeled with either wax pencil or some type of adherent label suitable for inscription. Blood slides may be labeled very readily by writing across the thick part in pencil; another method is to scratch the identification with the puncture point in very small letters across the beginning end of the blood film. In such manner a permanent label is obtained. Individual pipets may be labeled with special tubing, or the laboratory request slips may be attached to the pipets.

NUMERICAL COUNTING OF ERYTHROCYTES AND LEUKOCYTES

1. Counts should be taken in the morning while the patient is still in bed. Violent movement, work, or exercise may provoke temporary pictures which are not normal. Food or prolonged fasting usually increases the count. If consecutive counts are made, they should be made at the same hour each day.

2. Assemble the following material:

   (a) Sterile puncture point
   (b) Ether and alcohol
   (c) Red and white counting pipets, which should be dry
   (d) Red counting solution and white counting solution, previously filtered
   (e) Small tubes or watch glasses for holding the counting solutions

Preparation of patient: Cleanse the ear lobe with ether to produce hyperemia. If alcohol is used, it may cause the cells to change shape. Ether cleanses and at the same time produces hyperemia. If the finger is to be used, disinfect the skin with ether or alcohol and dry. If venous blood is used, transfer to special anticoagulant and mix thoroughly to prevent clotting.

"Duets" sterile wrapping containers for syringes (courtesy Central States Paper & Bag Co., St. Louis, Mo.). Hemolets for finger puncture, sterile needles, cotton balls and antiseptic, and appropriate containers for blood specimens, pipets for individual blood samples (courtesy Veterans Hospital and Jewish Hospital, St. Louis, Mo.).

Technic of puncture: This technic is explained on p. 1099.

NUMERICAL COUNTS OF ERYTHROCYTES

Equipment:

1. Blood specimen.
   This may be capillary or venous oxalated blood.

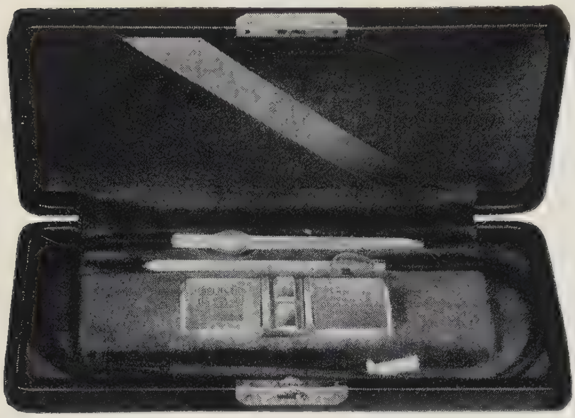

Fig. 348. Complete hemacytometer including improved double Neubauer counting chamber. (Courtesy American Optical Co., Scientific Instrument Division, Buffalo, N. Y.)

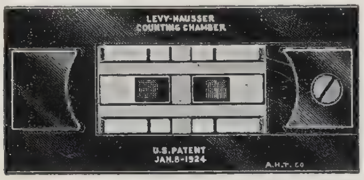

Fig. 349. Levy-Hausser counting chamber mounted in molded bakelite holder, forming a practically unbreakable unit. (Courtesy Arthur H. Thomas Co., Philadelphia, Pa.)

2. Red blood cell diluting pipet.
   There are 2 types of red counting pipet, the standard Thoma and the Trenner. The Thoma pipet illustrated in Fig. 354 has 10 divisions on the capillary end, with 0.5 and 1 points numbered prominently. If blood is drawn to the 0.5 mark and the pipet is filled with diluting fluid, the resultant dilution is 1:200 (1 vol. of the 101 total remains in the stem, does not enter the bulb, is blown out first before the counting chamber is filled, and therefore does not dilute the blood). This is the dilution used in routine counting. If the patient is quite anemic, a lesser dilution may be made by drawing the blood to the 1 mark and then filling the pipet with diluting fluid, a dilution of 1:100. Obviously, various dilutions may be obtained by using the different divisions on the capillary or stem for measuring the amount of blood to be used. The Trenner or automatic pipet is so constructed that when blood is drawn into the capillary end it will be carried by capillary attraction to a given point in the capillary. These pipets permit only 1 dilution, 1:200.
3. Hemacytometer.
   A counting chamber basically consists of a glass plate upon which have been etched lines, permitting accurate measurement of small volumes of blood. Fig. 348 illustrates one such hemacytometer. Fig. 351 shows the ruling of a single counting chamber. The most commonly used ruling is the improved Neubauer (Fig. 350, *5*). This ruling has been reproduced in Fig. 353. Note that a single chamber (of which there are usually 2 per hemacytometer) consists of 9 large squares, each measuring 1 sq.mm. Each of these squares covers a low-power field (16 mm. objective, 10× ocular). The central square of the chamber is subdivided into 25 smaller squares (each $\frac{1}{25}$ sq.mm.), 5 of which are marked **R** in Fig. 353. Each of these 25 squares is further

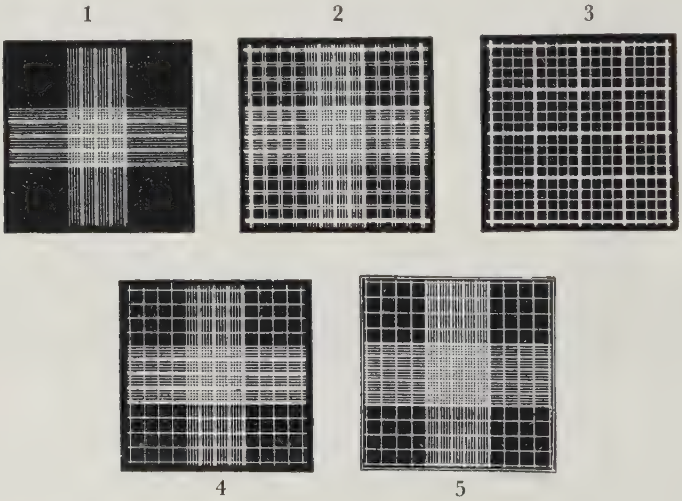

Fig. 350. Hemacytometer counting chamber rulings: **1**, Thoma; **2**, Tuerk; **3**, Fuchs-Rosenthal; **4**, Neubauer; **5**, improved Neubauer. (Courtesy E. H. Sargent Co., Chicago, Ill.)

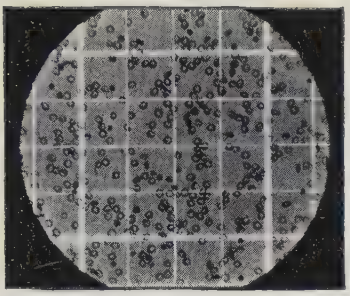

Fig. 351. Bright line counting chamber. (Courtesy American Optical Co., Scientific Instrument Division, Buffalo, N. Y.)

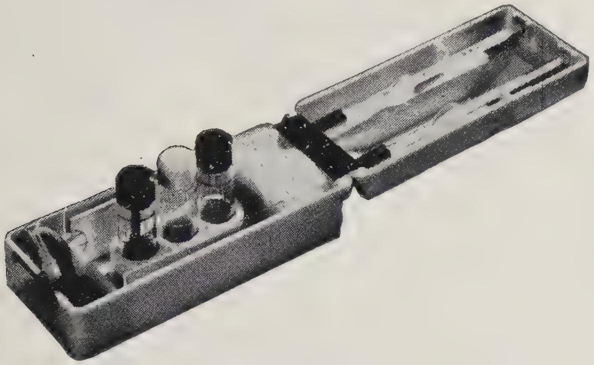

Fig. 352. Bard-Parker hematologic case.

divided into 16 squares ($\frac{1}{400}$ sq.mm. each). The 5 squares marked **R** are used for routine erythrocyte counting. A magnification of one of these **R** squares containing erythrocytes is illustrated in Fig. 351. One of these $\frac{1}{25}$ sq.mm. fields covers a high dry (4 mm. objective, 10× ocular) field.

Formula for determining factors in hemacytometry:

$V = D \times Dp \times S.A.$

V is the volume of blood actually measured.

D is the dilution of the blood sample (variable).

Dp is the depth of the counting chamber ($\frac{1}{10}$ mm.).

S.A. is the surface area counted (variable).

The formula for correcting counts to the number of cells/c.mm. whole blood is as follows:

$$C = N \times \frac{1}{V} \text{/c.mm.}$$

C is the cell count per c.mm.

N is the number of cells actually counted in the chamber.

V is the value from the formula above.

Example of how to use these formulas is given on p. 1105.

These formulas are applicable to any cell counting performed in a hemacytometer.

4. Hemacytometer cover glass.
   This is especially designed for this purpose. Do not substitute ordinary laboratory cover slips.
5. Microscope.
6. Carrying case for hematologic outfit.
   It is frequently necessary to collect blood for red and white counts outside the laboratory, hospital, or physician's office. Under these circumstances, the use of the Bard-Parker hematologic case* or some similar device is recommended (Fig. 352).

Reagents:

1. Diluting fluid. Hayem red cell counting solution.

Mercuric chloride, c.p. . .	0.5	gm.
Sodium sulfate, c.p., crystalline	5	gm.
or anhydrous	2.65	gm.
Sodium chloride, c.p. . .	1	gm.
Distilled water	200	ml.

Dissolve all the chemicals in the distilled water and filter several times through the same filter paper. Make a sufficient supply for only 2-3 wk., since deterioration might occur beyond this time, although Hayem solution is fairly stable. If a precipitate forms, discard the solution. This solution must be used at room temperature to prevent clumping of the erythrocytes due to the cold. **Clumping of the erythrocytes** may also occur in diseases associated with hyperglobulinemia, such as multiple myeloma, lymphomas, etc. It has been recommended that 0.01 gm. gelatin be added to each 100 ml. solution to prevent such agglutination.[82]

2. Gower diluting fluid.

Glacial acetic acid . . .	16.65	gm.
Sodium sulfate, c.p., crystalline	6.25	gm.
Distilled water	100	ml.

Add the ingredients slowly to the distilled water and mix thoroughly. It has been claimed[83] that Gower solution prevents rouleaux formation of the erythrocytes.

Taking red cell count:

1. If capillary blood is obtained from a skin puncture, wipe off the first drop with a piece of dry sterile cotton and use successive drops obtained without undue squeezing of the part, working rapidly to prevent clotting of the blood. If oxalated blood is used, it must be thoroughly mixed prior to use, preferably mechanically on a tube rotator.†
2. Make the dilutions of blood as perfectly as possible.
3. Holding the pipet **up** at an angle of 45° in the drop of blood and not touching the skin, draw the blood to exactly the 0.5 mark of the counting pipet (for routine counts). Always draw the blood into the pipet; never allow it to run in by capillary attraction.
4. Wipe the tip of the pipet clean of blood with a piece of dry cotton, gauze, or filter paper, without touching the opening of the capillary, and then immerse in the freshly filtered diluting fluid, which should be in a small tube or a watch glass. Do not insert the pipet in a bottle of counting solution.
5. Draw the diluting fluid steadily into the pipet by gentle mouth suction to exactly the 101 mark past the bulb of the pipet, rotating the pipet on its long axis to ensure thorough mixing of blood and diluent and gradually getting the pipet into a vertical position so that the measurement at the top of the pipet

---

*Bard-Parker Co., Inc., Danbury, Conn.

†Baltimore Biological Laboratory, Baltimore, Md.

may be accurate. Do not permit the capillary tip of the pipet to come out of the diluting fluid while drawing up the solution, and do not permit any of the blood to run out of the capillary while filling the pipet. If the diluting fluid has been permitted to go beyond the 101 mark, or if air bubbles are present in the pipet, discard the mixture and begin again with a clean, dry pipet.

6. Immediately mix the contents of the pipet thoroughly by placing the thumb over one end and the first finger over the other end and shaking for a minute or so.

The diluted blood may be transported to the laboratory for further examination. Take care that none of the fluid escapes from the pipet. Lay the pipet on its side and avoid touching the tip to any object. Various devices including wide rubber bands and pipet tubing have been used for sealing the pipet. Pipet closures are available commercially. If rubber bands are used, seal off the small capillary end of the pipet first to prevent expulsion of fluid. In removing the device, reverse the procedure. When picking up the pipets for manual shaking, follow the same order of holding the pipets.

Diluted blood samples may be examined within 2 hr. However, these must be thoroughly mixed just prior to their admission into the hemacytometer.

Filling the counting chamber:

1. Shake the pipet for 2 or 3 min., holding it in one hand and striking it gently against the opposite hand. Mechanical shakers are available commercially and are highly desirable, particularly in a laboratory doing a large volume of work.
2. Thoroughly cleanse the hemacytometer and cover slip and render dry and fat-free. After use, wash in running cold water and wipe dry with fine gauze, lens paper, or linen. Avoid touching surfaces which are to come in contact with the blood specimen.
3. Place the cover slip in its proper position over the ruled areas of the hemacytometer and examine the assembled instrument for cleanliness under the low power of the microscope.
4. Discard the first 3 or 4 drops of diluted blood from the pipet and then fill the counting chamber by capillary attraction by placing the tip of the pipet at one of the open ends of the chamber. The angle of the pipet and the time required for filling the chamber vary with the speed of the pipet and can be determined only by experience. Carefully fill the counting chamber exactly. Overfilling can be readily observed by the presence of fluid in the moats surrounding each ruled area. If this occurs, clean the instrument and refill the counting chamber. An insufficient amount of fluid may be noted by the failure of fluid to cover a ruled area. Rectify by adding more fluid to the chamber. If air bubbles are present in the chamber, they usually indicate lack of cleanliness of the hemacytometer or cover slip or moisture. Clean again and refill the chamber.

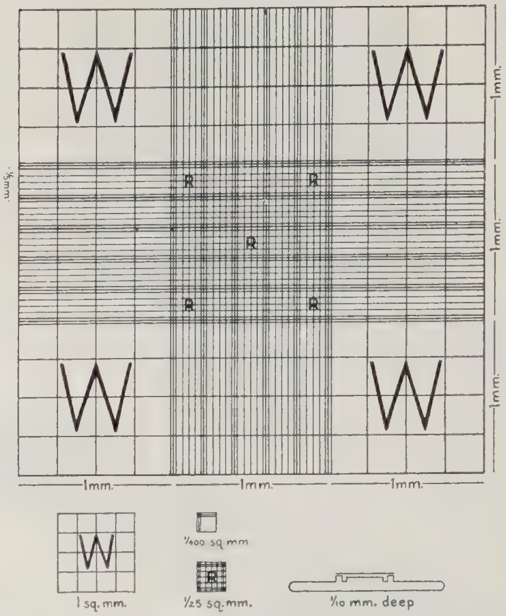

Fig. 353. Counting chamber rulings and dimensions.

5. Fill both ruled areas successively.
6. Allow the mixture to settle in the chamber. Locate the ruled area for erythrocyte counting under low magnification and then change to the high dry objective for actual counting of the cells.

Making the count: In a routine erythrocyte count, enumerate the cells in the five **R** squares (Fig. 353). Since Hayem solution does not dissolve leukocytes, do not count such cells in the red blood cell count. Leukocytes are larger than erythrocytes, appear grayish, and are usually granular. Only one such cell is seen in approximately 750-1000 erythrocytes; therefore leukocytes do not present a problem in routine red cell counting. When the white count is very high, particularly in leukemia, it is very important to make this differentiation.

A standardized pattern of counting should be adopted. It is recommended that counting begin in the left upper corner of each **R** square and proceed as follows. Count the first row of small subdivisions to the right, drop down to the second row and count to the left, drop down to the third row and count across to the right, and then finish the fourth row counting to the left. In the enumeration include all cells touching or half in and half out of the upper line and the line to the left, excluding those half in and half out of the lower and right-hand lines. Take care not to count any cell twice and do not omit any cells. **Remember that the boundary line is the center line of the triple ruling.** Count the first **R** square at the upper left of the ruling, the second at the upper right, the third at the lower right, the fourth at the lower left, and the fifth in the center (Fig. 353).

Record the count in each **R** square and obtain the sum of the cells in the 5 squares. (Mechanical counters are available commercially.)

Count 2 such chambers and take the average.

Calculation:

Example for routine counting: Multiply the sum of the 5 squares by 10,000.

454 cells counted in 5 **R** squares in 1 chamber.
456 cells counted in 5 **R** squares in the second chamber.

2) 910

455 cells counted in an average of 5 **R** squares.

Dilution of the blood 1:200. Area counted $\frac{5}{25}$ or $\frac{1}{5}$ sq.mm.

$V = \frac{1}{200} \times \frac{1}{10} \times \frac{1}{5} = \frac{1}{10{,}000}$ c.mm.

$$C = 455 \times \frac{1}{\frac{1}{10{,}000}}$$

$= 455 \times 10{,}000$

$= 4{,}550{,}000$ erythrocytes/c.mm. blood.

For anemic blood: Blood was drawn to the mark 1 in the pipet, making the dilution of blood 1:100.

455 cells were counted in the 5 **R** squares.

$V = \frac{1}{100} \times \frac{1}{10} \times \frac{1}{5}$ c.mm. $= \frac{1}{5{,}000}$ c.mm.

$$C = 455 \times \frac{1}{\frac{1}{5{,}000}} = 455 \times 5{,}000 = 2{,}275{,}000$$

erythrocytes/c.mm.

For extremely anemic blood: Blood was drawn to the mark 1 in the pipet, making the dilution of blood 1:100.

455 cells were counted in 10 **R** squares in each drop.

$V = \frac{1}{100} \times \frac{1}{10} \times \frac{10}{25} = \frac{1}{2{,}500}$ c.mm.

$$C = 455 \times \frac{1}{\frac{1}{2{,}500}} = 455 \times 2{,}500 = 1{,}137{,}500$$

erythrocytes/c.mm. blood.

For polycythemic blood: Blood was drawn to the 0.4 mark in the pipet, making a dilution of 0.4:100 or 1:250.

600 cells counted in 5 **R** squares.

$V = \frac{1}{250} \times \frac{1}{10} \times \frac{1}{5} = \frac{1}{12{,}500}$ c.mm.

$$C = 600 \times \frac{1}{\frac{1}{12{,}500}} = 600 \times 12{,}500 = 7{,}500{,}000$$

erythrocytes/c.mm. blood.

During the counting process observe the distribution of the erythrocytes. If clumps of cells are seen, the distribution is unsatisfactory, and an entirely new dilution of blood is required. If motion continues in the preparation in a streamlike fashion, counting is inaccurate. Such motion may result from overfilling or underfilling the chamber or from drafts caused by fans or open windows. These features must be corrected or eliminated.

Observations in the counting chambers should not be limited to merely tallying the numbers of red blood cells. Examine the relative size and shape of the erythrocytes. Normally there is uniformity of size and shape of the cells. In pathologic blood, lack of uniformity is often apparent.

As soon as the count has been made, clean the hemacytometer and cover slip in cold running water and dry with a clean lint-free cloth or lens paper. Do not allow preparations in the counting chamber to dry and do not perform counts on specimens which are drying. Clean the pipets immediately, or if that is impossible, empty them and fill at once with distilled water until such time as they can be cleaned.

Normal:

Males: 4,600,000-6,200,000/c.mm.; average 5,400,000

Females: 4,200,000-5,400,000/c.mm.; average 4,800,000

The normal values in children are somewhat different.

NUMERICAL COUNTS OF LEUKOCYTES

Equipment:

1. Blood specimen.
   This may be capillary or venous oxalated blood.
2. White blood cell diluting pipet.
   There are 2 types of pipets, the classic Thoma and the Trenner. The Thoma pipet, (Fig. 354) has 10 divisions on the capillary end with 0.5 and 1 prominently scored. Beyond the bulb is another mark, 11, which indicates the level to which diluting fluid is drawn. If blood is drawn to the 0.5 mark, the resultant dilution is 1:20 (1 vol. of the total 11 vol. remains in the stem and is blown out before the counting chamber is filled, leaving a total of 10 vol. diluted blood). For routine leukocyte counting a dilution of 1:20 is used. If marked leukopenia is present, a lesser dilution may be obtained by drawing blood to the 1 mark, a dilution of 1:10. Various dilutions to suit particular conditions may be obtained by drawing blood to any of the other divisions on the capillary pipet. The Trenner or automatic pipet permits of only 1 dilution, 1:20.
3. Hemacytometer. This is described on p. 1102.
   The four corner squares marked **W** in Fig. 353 are counted routinely. These are 1

1 VOLUME DILUTING FLUID REMAINS IN THE STEM AND DOES NOT DILUTE BLOOD

Fig. 354. Explanation of dilution of blood in red and white counting pipets.

sq.mm. each. One square covers a low-power dry objective field with a 10× ocular (16 mm. objective). The formula for determining factors in hemacytometry is given on p. 1103.

4. Hemacytometer cover glass (use no substitute).
5. Microscope.

Reagents:

1. Diluting fluid—1 or 2% acetic acid.
   Use 1 ml. (or 2 ml.) glacial acetic acid for each 100 ml. counting solution. Filter 3 times through the same filter paper. The solution must be made fresh at least once a week. The addition of a few drops of methylene blue or brilliant cresyl blue to 100 ml. of the solution will stain the leukocytes and aid in visualizing them under the microscope. Filter again immediately before use.
2. N/10 Hydrochloric acid.
   This diluent is used routinely when the Haden-Hausser hemoglobinometer is used. No dye should be added to this solution. Method of making normal solutions is given on p. 15.

Procedure:

1. Prepare the patient as directed on p. 1101 and make the puncture. Wipe off the first drop of blood.
2. Draw the blood to mark 0.5 (for routine counting) in the capillary end of the pipet and the counting solution to mark 11. Use the same technic as described for red blood cell counting. Be sure to wipe the blood off the outside of the pipet before immersing the pipet in the watch glass containing the counting solution.
3. Shake as for a red count, allow several drops to leave the pipet, and immediately fill both sides of the counting chamber.
4. Focus under low-power dry magnification, preferably with the condenser removed or lowered. Adjust the light so that the leukocytes appear as slightly iridescent round bodies with a very definite outline. If there is doubt as to whether an object is a leukocyte or an artifact, look at it under high magnification. Leukocytes have definite cell outlines and well-defined nuclear structure. Platelets appear as very small refractive bodies about one-fifth to one-seventh the size of the leukocytes, with no nuclei and slight brownian movement. Erythrocytes should not be present because the diluting fluid should hemolyze them. Occasionally ghost outlines of red cells may be seen.
5. For routine counting, enumerate the cells in the 4 corner **W** squares, each divided into 16 smaller squares for convenience in counting. Count first the upper left **W** square of 16 small squares, then the upper right, the lower right, and last the lower left. The enumeration should follow the same pattern described under erythrocyte counting. Include in the count those leukocytes which are half in and half out of the upper and left-hand lines, but not those half in and half out of the lower and right-hand lines. Remember that the boundary line is the center line of the triple ruling.
6. Count 2 such drops, one in each side of the counting chamber.
7. Record the counts and obtain the sum. Or use a mechanical counter.

Calculations:

For routine leukocyte counts: Multiply the count of 4 **W** squares by 50.

194 cells counted in the first count.
198 cells counted in the second count.
2) 392 cells
196 leukocytes counted in 4 **W** squares.

Dilution of the blood 1:20; area counted 4 sq.mm.

$V = \frac{1}{20} \times \frac{1}{10} \times 4 = \frac{1}{50}$ c.mm.

$C = 196 \times \frac{1}{\frac{1}{50}} = 196 \times 50 = 9{,}800$ leukocytes/c.mm.

Comment: **In routine leukocyte counting only,** in which 4 **W** squares are counted, the mathematics may be simplified by dividing the number of cells counted in a total of 4 **W** squares by 2 and adding two 0's. An average of the 2 counts must be made.

Example for leukopenic blood:

98 leukocytes counted in 8 **W** squares

Dilution of blood 1:10 (blood drawn to mark 1 instead of 0.5)

Area counted 8 sq.mm.

$V = \frac{1}{10} \times \frac{1}{10} \times 8 = \frac{8}{100}$ c.mm.

$C = 98 \times \frac{1}{\frac{8}{100}} = \frac{9{,}800}{8} = 1225$ leukocytes/c.mm.

Example for blood with leukocytosis:

600 cells counted in 4 **W** squares (4 sq.mm.).

Dilution of blood 1:33 (blood drawn to 0.3 mark in pipet).

$V = \frac{1}{33} \times \frac{1}{10} \times 4$ c.mm. $= \frac{4}{330}$ c.mm.

$C = 600 \times \frac{1}{\frac{4}{330}} = \frac{600 \times 330}{4} = 49{,}500$ leukocytes/c.mm.

Normal:

Adults: 4500-11,500/c.mm.; average 7400

Comments: In instances in which leukocyte counts exceed 50,000/c.mm., dilutions may be made in the red cell diluting pipet, using white counting solution. If blood is drawn to the 1 mark in the red pipet, the dilution is 1:100.

If a specimen is taken routinely in the white counting pipet and it is found that the count is too high to enumerate accurately, and if the patient is not available for another dilution to be made, count the cells under high magnification in the center square (the one divided into 400 small squares), counting all the cells in the entire 25 squares or 1 sq.mm. Do not take an average. The area counted is 1 sq.mm., the dilution of blood is 1:20, and the depth of the counting chamber is $\frac{1}{10}$ mm.

Multiply the sum of the cells by 200.

During the counting process, observe for equality in distribution of the cells. If clumps are present, the distribution is unsatisfactory, and an entirely new dilution of blood is required.

As soon as tallying has been completed, clean the hemacytometer and cover slip in cold running water and dry with a clean lint-free cloth or lens paper. Do not allow specimens in the counting chamber to dry and do not perform counts on preparations which are drying. Clean the counting pipets immediately, or if that is not possible, empty them and fill with distilled water until such time as they can be cleaned.

Historical: The procedure of counting the total number of white cells in the blood seems to have been initiated by Malassez in 1872.[84] The method of studying the white and red cells was worked out further by Gowers in 1877; by Thoma in 1882, who used the red pipet and modified it for the leukocytes, thus giving us the pipet so universally used ever since; by Alferow in 1884, who distinguished white cells by raising the tube to lengthen focal distance; and by Toisson in 1885, who used a fluid permitting the counting of white cells in the same pipet with red cells. This ideal was pursued by Schüffner further in 1911 and Türk in 1912. Zappert in 1892 worked out the first satisfactory ruling for the counting chamber. Rieder in 1892, Elzholz in 1894, Friedlander in 1897, Durham in 1897, Einhorn and Laporte in 1902 (white count being made directly from film, by noting the ratio of white cells to red cells and counting only the red cells in chamber), Türk in 1902, Breuer in 1902, Joffroy and Mercier in 1902, Engel in 1902 (differentiation of white cells by refraction of light, most like Alferow), Burker in 1905 and in 1907, Ellermann and Erlandsen in 1909, Dunger in 1910, Galambos in 1910, Hill in 1912, and Roderdansz in 1913 further worked out the details of counting white cells.

Making numerical counts of leukocytes in blood showing large numbers of nucleated red cells

There are some conditions accompanied by an influx of nucleated red cells into the blood stream. When leukocyte counts are made of such bloods, it is often difficult and sometimes impossible to differentiate under low magnification between leukocytes and nucleated red blood cells that are not dissolved by acetic acid. These cells might therefore be included in the total leukocyte count. If the peripheral spread shows many nucleated red cells, the total leukocytes counted should be corrected for their number.

Correcting leukocyte count for nucleated red blood cells: Determine the number of nucleated red cells/100 white blood cells in the peripheral blood film and then use the formula in the example below to determine X, which must be subtracted from the uncorrected total white blood cell count in order to give the corrected white blood cell count.

The corrected leukocyte count = the total uncorrected leukocyte count − X (the absolute number of nucleated RBC/c.mm.). The value for X is calculated as follows:

$$X = \frac{\text{No. nucleated RBC/100 uncorr. WBC}}{100 + \text{No. nucleated RBC/100 uncorr. WBC}}$$

× Uncorr. WBC/c.mm.

Example:

Uncorrected blood count = 19,500

25 nucleated RBC/100 actual cells as counted on blood film

$$X = \frac{25}{100 + 25} \times 19{,}500 = 3900$$

Corrected WBC count = 19,500 − 3900 = 15,600.

CLEANING THE PIPET

Eject the contents of the pipet immediately after using. Never allow the blood to remain in the pipet, as this might cause permanent blockage. Use a suction pump to clean the pipet, drawing the following various solutions through it.

Wash thoroughly with distilled water until all traces of blood have been removed. Next, draw alcohol through the pipet to remove the water. Next, draw ether through the pipet to remove the alcohol and to dry. Continue the use of suction until the pipet is thoroughly dry, as evidenced by the jumping of the glass bead in the bulb. If the glass bead adheres to the side of the bulb, the pipet still contains moisture which must be removed with alcohol and ether.

Ammonia water, potassium hydroxide, or N/10 hydrochloric acid may be used in cleaning the pipet, provided that all traces of the chemical employed are removed before the pipet is used again.

Some laboratories prefer to clean the pipets with distilled water, followed by acetone drawn through the pipets, and then an air current to dry them.

Caution! If the pipets are set aside after the dilutions are made, the contents must be thoroughly mixed before filling the counting chamber, as the cells will tend to settle at the bottom of the bulb, and subsequent counts without mixing will be inaccurate.

In making counts, count all cells within the ruled area and in addition all cells which lie along the ruled lines at the top and left side of the field. Omit all cells lying on the bottom and right sides unless they are definitely within the ruled area. Remember that the center line of the triple ruling is the border of the field in some counting chambers. One must study the rulings to distinguish between guide lines and boundaries of fields.

PRECAUTIONS TO BE OBSERVED IN MAKING RED AND WHITE COUNTS AND BLOOD FILMS

1. Always remove the first drop or two of blood that oozes out after the skin puncture. Always remove the blood that is left between taking of the various specimens, such as red and white counts, films, etc.
2. Never under any circumstances squeeze to obtain blood.
3. Hold the pipets either vertically or up at a 45° angle; never allow them to hang down from the puncture.
4. If blood clots occur in the red and white counts, in spreads, thick drop, or hemoglobin test, repeat the preparations to avoid inaccuracies.
5. Be sure to draw the blood for red and white counts and hemoglobin exactly to the mark on the pipet—never above nor below.
6. Be sure that no air bubbles enter the pipet during the diluting process.
7. Always be sure there is no blood on the outside of the pipet before drawing up the counting solution.
8. Shake the pipets for several minutes before filling the counting chamber, but do not shake them too hard.
9. Eject several drops of diluted blood from the pipet before filling the counting chamber. If more than 1 drop of the dilution is counted, the pipet must be shaken before filling the counting chamber the second time, and several drops of the dilution must be ejected.
10. Never overfill nor underfill the counting chamber. If air bubbles are present, clean the counting chamber and refill. If the counting chamber is imperfectly overfilled, clean the counting chamber and refill with a fresh drop.
11. It is well to take the specimens for the complete blood picture in the following order: films, white count, red count, thick drop, and hemoglobin.
12. Under no circumstances allow the pipets for red and white counts and hemoglobin or the slides for films and thick drops to touch the skin.
13. When diluting the red and white counts, be sure that no blood runs back out of the pipets while drawing up the diluting fluid.
14. Keep blood films and thick drops out of dust and away from flies and other insects.
15. Always make the counts as soon after taking the specimen as possible.
16. Use fresh counting solution for each count. Filter enough solution into a watch glass or small tube to be used for diluting 1 count. Do not dip the pipet into the stock bottle of counting solution.
17. Never use oxalated or heparinized blood for making blood films.

The sources of error of red and white cell counting are numerous. Some can be eliminated by adherence to the points just mentioned; others are inherent to the method and can be minimized only by counting large numbers of cells, e.g., 2000.

There are errors which are due to the methods of collecting and handling of the blood, whereas others are due to the equipment and its handling, and finally some are statistical errors, as when a small quantity is used to represent a large mass. The average error of the red cell count, using excellent technic, is ± 11%. This error may increase to ± 22%.

In the white cell count, in which the usual dilution is not as great as in the red cell count, the error is about ± 15%.

Because of the relatively large possible error of the method, each laboratory should establish a standard deviation of these methods in order to better evaluate the accuracy of blood counts and to better interpret fluctuating repeated counts on a given patient.

The method of calculating the standard deviation as a means of evaluating the variations of results of a particular method applies to all laboratory work and is not restricted to hematology.

ELECTRONIC COUNTERS[35-39]

An electronic counter* counts the individual red blood cells of a measured volume of diluted blood as they pass through a minute orifice guarded by an electric current flowing between platinum electrodes. The red blood cells, which are poor electrical conductors, in passing through the orifice displace an electrically conductive 0.9% saline solution in which they are suspended and thus modulate the electric current.

The modulations are amplified and counted.

---

*Coulter Electronics, Chicago, Ill.

They depend on the number and size of the cells passing through the orifice. The counter works with an accuracy and reproducibility of about 2%. The electronic counter enumerates red and white blood cells alike, and an error will be introduced if leukocytosis of over 30,000 cells/c.mm. exists. In this case the result must be corrected. The electronic counter can also be used in enumerating leukocytes and platelets and accomplishes that with a standard error of 2.8%.

Recently the use of a stable suspension of latex particles of known size and concentration has been described as a device for monitoring electronic counting instruments.

HEMOGLOBIN DETERMINATIONS

Hemoglobin is an iron-bearing protein which is the red coloring matter of the blood. Discussion of hemoglobin is found on pp. 1080 and 1081.

Normal:

Adult males: 14-18 gm./100 ml. blood; average 15.8.

Adult females: 11.5-16 gm./100 ml. blood; average 13.9.

METHODS IN HEMOGLOBINOMETRY

There are 4 basic methods of measuring hemoglobin content of the blood.

A. Colorimetric
   1. Hemoglobin examined directly as oxyhemoglobin by the methods of Dare, Tallqvist, and Spencer instrument and the photoelectric method
   2. Hemoglobin converted to acid hematin by the methods of Sahli, Newcomer, Haden-Hausser, and LaMotte and the photoelectric method
   3. Hemoglobin converted to alkaline hematin in photoelectric methods
   4. Hemoglobin converted to CO-hemoglobin by the method of Haldane
   5. Hemoglobin converted to cyanmethemoglobin
   6. Hemoglobin converted to pyridine hemochromogen
   7. Hemoglobin directly matched with artificial standards

B. Physical
   1. Physical measurement of specific gravity of whole blood and serum or plasma by the copper sulfate method
   2. Hematocrit

C. Gasometric measurement of oxygen capacity of blood (method using Van Slyke apparatus)

D. Measurement of iron content of blood by chemical means

The methods are further subdivided into those that lend themselves to routine clinical use and those that are accurate enough to be utilized for checking the accuracy of the routine clinical method (methods of standardization).

ROUTINE CLINICAL METHODS

Colorimetric methods

Dare method

Instrument is standardized so that 16 gm./100 ml. blood is the equivalent of 100% hemoglobin.

Principle: The Dare hemoglobinometer is based on the principle that the color of a thin film of undiluted blood illuminated by a standard light source may be compared with a graduated nonfading color scale built into the apparatus. Models are available in both battery or electrically operated light sources. The matching fields are supplied in 2 types, regular or juxtaposition fields.

Procedure:

1. Prepare the instrument by placing the 2 pieces of glass (1 frosted and 1 plain) together and inserting them into the small metal holder.
2. Make a puncture in the usual manner, discarding the first drop of blood. Allow the blood to run into the space between the 2 pieces of glass; then place the specimen in the instrument so that the white glass will be toward the source of light.
3. Look through the telescope, holding the hemoglobinometer in a position which allows the light to penetrate the blood specimen.
4. Revolve the standard by turning the knurled knob at the top of the instrument, until the

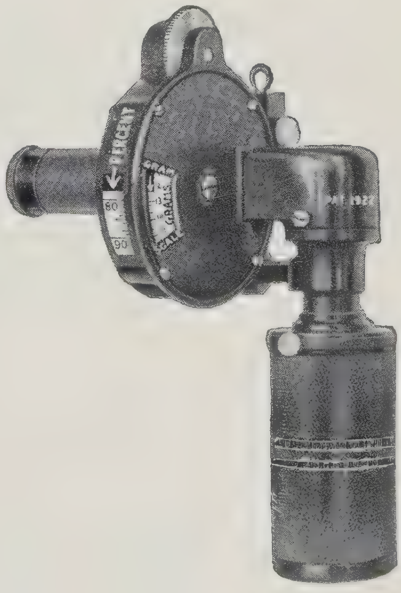

Fig. 355. Dare hemoglobinometer with gram scale. (Courtesy Rieker Instrument Co., Philadelphia, Pa.)

color of the unknown exactly matches that of the standard.
5. Read from the graduation marks at the side of the instrument the percentage or gm. hemoglobin.
6. To convert to gm. hemoglobin/100 ml. blood, multiply the percentage of hemoglobin by 16 or convert to gm. by reading directly off the scale.

Example:
Percentage of hemoglobin is 95.
0.95 × 16 = 15.20.
After use, the instrument should be cleaned and dried immediately.

This method of direct matching is subject to considerable error and is therefore not recommended.

Spencer hemoglobinometer

The Spencer* hemoglobinometer is a pocket-sized instrument operated by battery or electric current and is convenient for determining hemoglobin concentration. It utilizes light in the visible green spectrum. In addition to the hemoglobinometer, hemolysis applicators are needed. This method is subject to the errors of all direct matching methods.

Procedure:
1. Place a large drop of blood from a skin puncture directly onto the open glass chamber of the apparatus. Hemolyze it completely with a hemolysis applicator until blood change is apparent. This takes approximately 45 sec. Close the chamber by sliding it under the cover glass and insert into the instrument. The hemolyzed blood must entirely fill the chamber; there must be no air spaces.
2. Press the illuminating switch and observe through the eyepiece. There will be seen 2 halves of a circular field, one which is stationary and represents the standard and the other which is movable and represents the unknown. By moving the lever on the side of the instrument, the fields can be brought to match each other. It is well to take several readings until 2 consecutive readings are alike.
3. Read the hemoglobin concentration directly from the graduated scales on the side of the apparatus. There are 4 scales on the instrument: gm./100 ml., scale based on a standard of 15.6 gm./100 ml. blood, % scale on a basis of 14.5 gm., and % on a standard of 13.8 gm. The inclusion of 4 scale readings on this apparatus is magnificent testimony to the widespread confusion as to what level of hemoglobin concentration is normal.

Sahli method

The Sahli hemoglobinometer consists of a set of glass rods colored amber and is housed in a casing with a central aperture. Into this center fits a graduated tube with a scale reading in either grams of hemoglobin/100 ml. blood or percentage of hemoglobin. The Sahli pipet has a capacity of 20 c.mm. (0.020 ml.). N/10 hydrochloric acid is used to convert to acid hematin.

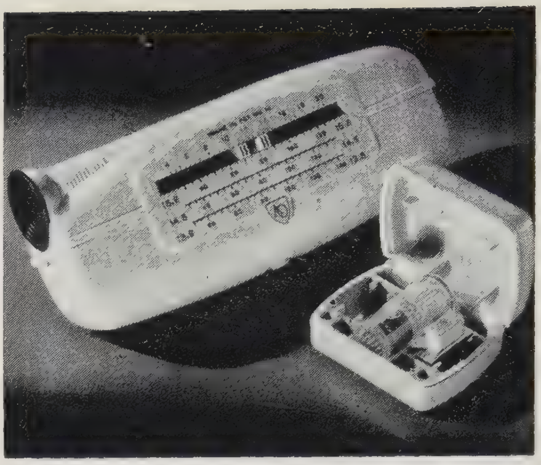

Fig. 356. Spencer hemoglobinometer. (Courtesy American Optical Co., Scientific Instrument Division, Buffalo, N. Y.)

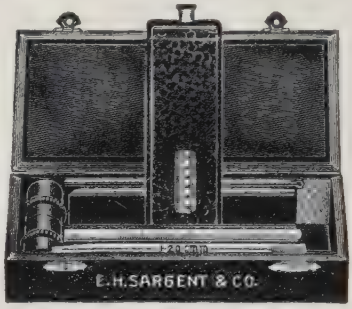

Fig. 357. Sahli hemoglobinometer. (Courtesy E. H. Sargent Co., Chicago, Ill.)

Procedure:
1. Prepare the instrument by placing N/10 hydrochloric acid in the graduated tube until the meniscus stands at mark 10 on the percentage scale.
2. Draw blood into the Sahli pipet to mark 20. Wipe the blood off the outside of the pipet.
3. Eject the blood into the hydrochloric acid solution and mix by drawing in and out of the pipet several times. Blow through the pipet while removing it from the tube.
4. Shake the tube and allow to stand a minimum of 1 min. and a maximum of 10 min.
5. Add distilled water a drop at a time, mixing after the addition of each drop, until the color in the tube corresponds exactly to the color of the standard. Do not go beyond the point at which exact color matching has occurred. If this happens, repeat the entire procedure.
6. Read in north daylight and turn the gradua-

---

*Scientific Instrument Division, American Optical Co., Buffalo, N. Y.

tions to the side in order to read through clear glass.

7. Read from the scale the percentage of hemoglobin. To convert to gm./100 ml. blood, multiply the percentage figure by the gram standard on the tube.

Normal: Sahli instruments have been on the market calibrated so that the normal values were 100% equivalent to 13.8, 14, 14.5, 17, 17.2, and 17.3 gm. hemoglobin/100 ml. blood.

Comment: This acid hematin method is simple. The apparatus is relatively inexpensive. The variety of standards is confusing, and the visual matching is subject to considerable individual variation. The pigment formation progresses at a variable speed, and the pigment forms a suspension rather than a solution. These criticisms also apply to the other acid hematin methods, such as the Newcomer and Haden-Hausser.

Newcomer method

The equipment consists of a standard Newcomer colored disk. Note the thickness inscribed on the disk. A Klett or Duboscq type colorimeter and a Sahli hemoglobin pipet are used.

Procedure:

1. Place the standard Newcomer disk in the Duboscq or Klett colorimeter preparatory to the reading of the hemoglobin test.
2. Place 5 ml. N/10 hydrochloric acid in a colorimeter cup.
3. Draw the blood to the 20 mark in a Sahli pipet.
4. Eject the blood into the hydrochloric acid and mix by drawing in and out of the pipet several times. Note the time at which the blood enters the acid solution.
5. Mix the contents of the cup well and allow to stand 10 min.
6. Have the cup below the standard disk filled with distilled water. Be sure the plunger enters the distilled water.
7. Match the colors in the colorimeter and obtain the reading. Calculate the gm. hemoglobin/100 ml. blood by dividing the reading in Table 227 by the reading on the colorimeter.

Table 227 takes into account the time which has elapsed before the reading was made and the thickness of the glass standard. The exact thickness of the glass disk is engraved on it.

Example:

10 min. elapsed before the reading was made.
Thickness of glass disk was 1 mm.
Reading on the colorimeter was 6.7.
99.4 ÷ 6.7 = 14.83.

Normal: The Newcomer standard is 16.92 gm. hemoglobin/100 ml. blood.

Haden-Hausser method[90]

The Haden-Hausser hemoglobinometer is manufactured in 2 models, the clinical and the laboratory. The basic principles and general design of the 2 instruments are essentially the same. The laboratory model is larger and features an electrically controlled light source. A miniature comparator scale graded from 7.5 to 19 gm. hemoglobin is built into a well in the apparatus. This is overlaid by a removable fitted glass cover slip which when in position directs the flow of the blood sample into the chamber.

A white blood cell counting pipet is used.

Procedure:

1. Dilute the blood 1:20 or 1:10 in a white blood cell counting pipet with N/10 hydrochloric acid.
2. Allow to stand at least 30 min. to complete conversion of the hemoglobin into acid hematin.
3. Run the diluted blood into the dilution channel of the comparator.
4. Move the comparator until a matching of the blood specimen and a colored segment of the comparator is found. Read values directly from the instrument.

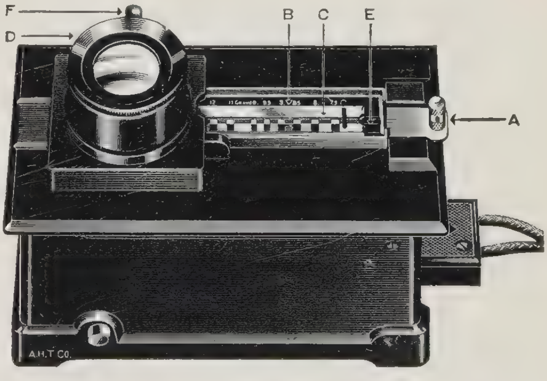

Fig. 358. Haden hemoglobinometer. (Courtesy Arthur H. Thomas Co., Philadelphia, Pa.)

Table 227

Minutes since dilution	Thickness of colored glass in ml.										
	0.95	*0.96*	*0.97*	*0.98*	*0.99*	*1.00*	*1.01*	*1.02*	*1.03*	*1.04*	*1.05*
10	93.4	95.4	96.4	97.4	98.4	99.4	100.4	101.4	102.3	103.4	104.4
15	93.1	94.1	95.0	96.0	97.0	98.0	99.0	100.0	101.0	102.0	103.0
20	92.5	93.5	94.5	95.4	96.4	97.4	98.4	99.4	100.4	101.3	102.3
30	91.8	92.8	93.8	94.8	95.7	96.7	97.7	98.6	96.6	100.5	101.5
40	91.6	92.5	93.5	94.5	95.4	96.4	97.4	98.3	99.3	100.3	101.2
Final	90.6	91.6	92.5	93.5	94.4	95.4	96.4	97.3	98.3	99.2	100.2

Normal: The Haden-Hausser standard is 16.7 gm. hemoglobin/100 ml. blood, which is equivalent to 100%.

Comment: An advantage of this method is that since the dilution of the blood is made in a white blood cell counting pipet both the leukocyte count and the hemoglobin estimation can be carried out with the same diluted blood specimen.

Photoelectric hemoglobin determinations based on measurement of oxyhemoglobin

The methods of determining hemoglobin by photoelectric colorimetry are given on p. 1109.

In the original method of Sheard and Sanford, which was the first photoelectric hemoglobin determination, 0.1% sodium carbonate was used as a diluent. The color of the resultant solution tends to fade within 3-4 hr. so that reading of the test must be made within this time limit. It has been found that 0.04% ammonium hydroxide will keep oxyhemoglobin solutions stable for as long as 4 days.[91] Hypotonic saline solutions have been generally abandoned as diluting fluids.

Normal: Normal values vary with the method and standardization of the photoelectric colorimeter. Values should preferably be expressed in gm. hemoglobin/100 ml. blood.

Photoelectric determination of hemoglobin based on measurement of acid hematin

The Fisher apparatus has an ammeter reading scale limited to percentage and gm.% hemoglobin. Any photoelectric colorimeter may be calibrated for this method. N/10 hydrochloric acid is used as the diluent. It takes about 30 min. for full development of the brown color; this time should be the minimum allotted for reading unknown samples.

Procedure:

1. Use either venous or finger blood.
2. Draw the blood into the hemopipet exactly to the graduation mark below the bulb and wipe the tip of the pipet clean.
3. Draw N/10 hydrochloric acid into the pipet to exactly the graduation mark above the bulb.
4. Allow the mixture to remain in the pipet for 30 min. or transfer it to the Fisher photometric cell and allow it to remain for 30 min.
5. Be sure that the pointer reads on the line marked **A.** Adjust by rotating the knob on the top of the instrument at the point marked **Adjust Zero.**
6. Turn the switch to **On** and allow the instrument to remain for 1-2 min. Insert the standardizing cell containing distilled water through the hole just in front of the reading scale. Turn the knob on the front panel and adjust the pointer to line **B.**
7. Remove the water-filled cell and replace with cell containing the blood specimen.
8. The pointer now indicates the hemoglobin concentration of the blood specimen both in gm. hemoglobin/100 ml. blood and in % normal.

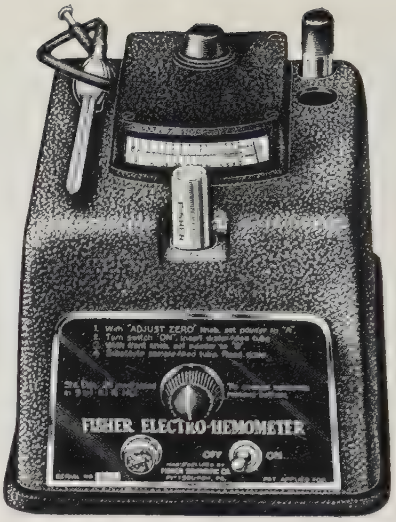

Fig. 359. Fisher Electro-Hemometer. (Courtesy Fisher Scientific Co., Pittsburgh, Pa.)

Normal: Normal values vary with the technic and standardization of the photoelectric colorimeter. The Fisher Electro-Hemometer (Fig. 359) uses a normal standard of 15.6 gm. hemoglobin/100 ml. blood.

Comments: This method has generally been discarded in favor of methods using oxyhemoglobin.

Methods in which hemoglobin is converted to alkaline hematin

These are photoelectric methods which basically measure dilutions of blood treated with alkali for conversion of hemoglobin to alkaline hematin. These dilutions are read photoelectrically, usually with a filter at 540 mμ. The instrument is calibrated against known solutions of hemoglobin. Graphs are prepared from the readings from known solutions, and unknown determinations are made from the graphs. Determination of hemoglobin based on alkaline hematin has not gained popularity and is rarely used. Fetal hemoglobin resists alkaline denaturation, and the alkaline hematin method is therefore not generally applicable.

Methods in which hemoglobin is converted to carbon monoxide hemoglobin (carbon monoxyhemoglobin)

The colorimeter may be the Duboscq type of visual colorimeter or a photoelectric instrument. This method employs artificial illuminating gas which is not generally available.

Reagents:

1. Ammonium hydroxide solution, 0.4%.
   Dilute 4 ml. ammonium hydroxide to 1000 ml. with distilled water in a liter volumetric flask.
2. Carbon monoxide.
   CO may be obtained by running a stream of illuminating gas through the specimen or by using commercially available tanks of carbon monoxide.

Normal: In the original Haldane methods the standard was 13.8 gm. hemoglobin/100 ml. blood.

Methods in which hemoglobin is converted to cyanmethemoglobin

Reagent:

1. Drabkin solution.[92, 93]

Sodium bicarbonate	1 gm.
Potassium cyanide	52 mg.
Potassium ferricyanide . .	198 mg.
Distilled water	1000 ml.

Ferricyanide oxidizes hemoglobin from ferrous iron to ferric iron to form methemoglobin in an alkaline medium. Methemoglobin interacts with potassium cyanide to form cyanmethemoglobin, a stable hemoglobin pigment. This reagent is available in pellet form* and is prepared by adding 1 pellet to 100 ml. distilled water.

Procedure:

1. Use a calibrated Sahli pipet to deliver 0.02 ml. capillary or venous oxalated blood to 5 ml. Drabkin solution in a dry cuvet. Rinse the blood out of the pipet repeatedly in the Drabkin solution. Mix by swirling the tube.
2. Allow the mixture to stand 10 min. If the mixture is turbid, add a pinch of saponin to hemolyze the red cells completely.
3. Use the diluent as a blank, set the wavelength at 540 mμ, and set the instrument at 100% transmission (% T) or zero optical density (OD).
4. Place the unknown into the instrument and record OD or T.

To find gm.% hemoglobin of the whole blood, refer to the standard curve. The standard curve can be prepared by using a commercially available cyanmethemoglobin standard.†

Comments: The cyanmethemoglobin method of hemoglobinometry has been recommended by a panel formed under the aegis of the National Research Council with a number of sponsoring groups.[94]

This method is precise and rapid. The results are somewhat on the high side of normal, as apparently other substances contained in blood besides hemoglobin react with potassium ferricyanide.

The use of a solution of cyanide in routine laboratory work poses the question of safety. Crosby et al.[95] take cognizance of this danger and recommend the following precautions:

"1. Pipets should be filled with a suction bulb.

"2. Blood should be mixed with the cyanide solution by swirling.

"3. If small amounts of cyanide compounds are accidentally spilled on the laboratory bench or on the floor during the weighing procedure, the dry powder should be wiped up with a damp cloth and discarded in a suitable container.

"4. Cyanide salts should be stored in a locked cupboard."*

The level of cyanide is far below the lethal dose. The lethal dose of Aculute is approximately 16 pellets to 4000 ml. diluent.

Calibration of cyanmethemoglobin method: A standard solution of cyanmethemoglobin is available commercially.† The concentration of cyanmethemoglobin is given in mg./100 ml. and is usually of the order of 60 mg. hemoglobin/100 ml. blood. The equivalence of this standard can be calculated as follows:

The dilution employed in the procedure just described is 1:251.

The equivalence of the standard in gm.% hemoglobin

$$= \frac{\text{Concentration Hb in standard} \times 251}{1000}$$

Example:

Concentration of hemoglobin in standard solution: 60.5 mg. Hb/100 ml.

$$\text{Equivalence of standard} = \frac{60.5 \times 251}{1000} = 15.2$$

gm.% Hb

Having calculated the value of the standard proceed as follows.

Prepare 5 cuvets: a blank tube containing 6 ml. diluent, tube 1 containing 6 ml. undiluted standard, tube 2 containing 4 ml. standard plus 2 ml. diluent, tube 3 containing 3 ml. standard plus 3 ml. diluent, and tube 4 containing 2 ml. standard plus 4 ml. diluent.

Determine the transmittance of tubes 1-4 using the blank tube as reference.

Make a semilogarithmic plot of % T obtained versus the hemoglobin equivalent of each dilution. The hemoglobin equivalent of each dilution is obtained by multiplying the hemoglobin equivalent of the undiluted standard by the appropriate dilution factor, i.e., tube 1 = 1.0, tube 2 = 0.666, tube 3 = 0.500, and tube 4 = 0.333.

Methods in which hemoglobin determinations are based on specific gravity of whole blood and serum or plasma

This method, frequently referred to as the copper sulfate method, is a useful rough guide in estimating hemoglobin concentrations and total proteins simultaneously. As a screening process it is of inestimable value, particularly when large numbers of determinations must be made. The method was developed during World War II and was popularized in the Armed Forces of the United States. It is not recommended as a routine clinical procedure.

Copper sulfate method to determine specific gravity of blood and hemoglobin content[95a]

This method makes it possible with 3 or 4 drops of blood, a medicine dropper, and small bottles of copper sulfate solution to determine the specific gravity of the blood and from it the hemoglobin content within 10%. The plasma protein concentration may also be determined. To measure the blood and plasma specific gravities and calculate the plasma proteins, hemoglobin, and hematocrit on the line charts requires about 2 min.

Principle: The technic consists of letting drops of plasma or whole blood fall into a graded series of solutions of copper sulfate of known specific gravity and noting whether the drops rise or fall in the solutions. Each drop on entering the solution becomes encased in a sack of copper proteinate and remains as a discrete drop without change of gravity for 15 or 20 sec., during which its rise or fall reveals its gravity relative to that of the solution. The size of the drop does not have to be constant; hence no special pipet is needed. No temperature correction is required. The copper sulfate solution automatically cleans itself after each test because within 1 or 2 min. after the test is completed the material of the drop settles to the bottom as a precipitate. The standard copper sulfate solutions are prepared by dilution of a stock solution of gravity 1.1000, which can be prepared either from weighed amounts of $CuSO_4 \cdot 5H_2O$, or by dilution from a saturated solution of the sulfate. The latter procedure makes it possible to prepare the standard solutions without a balance.

For accurate work a series of copper sulfate solutions graded at intervals of 0.001 in specific gravity is used; 21 solutions cover the plasma range 1.015-1.035 and 41 cover the whole blood range, 1.035-1.075. For rougher work with gravities accurate to ±0.001, 16 solutions at intervals of 0.004 suffice to cover the entire range of blood and plasma

Apparatus:

1. Apparatus for drawing and preparing blood.
2. Centrifuge (can be omitted if one can wait for blood to clot or sediment until a few drops of serum or plasma can be obtained).
3. Medicine droppers.
4. Oxalated test tubes, heavy-walled Pyrex, of about 10 ml. capacity (125 × 16 mm.). These are prepared in advance for 5 ml. portions of blood by pipetting into each tube 0.25 ml. of a 2% solution of 3:2 ammonium-potassium oxalate (see Reagents). The solution is spread in a film about the lower half of the tube and dried in an incubator (not over 50° C.) or in a vacuum desiccator. The tube is marked on the outside to hold 5 ml.
5. Bottles or tubes for standard copper sulfate solutions: One or more of the following sets will be needed.
    - (a) Laboratory set covering the ranges of blood, plasma, and transudates. Seventy oval or round bottles of 4 oz. capacity. This number will hold solutions covering the range 1.008-1.075 at 0.001 intervals and provide 3 spares. With these intervals the gravities can be estimated to ±0.0002. The 100 ml. portions of solution held by these bottles suffice for analysis of about 100 blood specimens and their plasmas The stoppers should be rubber, cork, or screw cap rather than glass, to prevent "freezing" and evaporation.
    - (b) Portable set covering the same range. One oz. bottles with screw caps. The 25 ml. portions of solution held by these bottles suffice for analysis of about 25 blood specimens and their plasmas.
    - (c) Field set for approximate analyses covering the range of blood and plasma. This includes 16 bottles to hold solutions covering the range 1.016-1.074 at intervals of 0.004. It serves for gravities within ±0.001. The bottles may be 1, 2, or 4 oz., according to the number of specimens of blood to be analyzed and the space and weight desirable for the set.
    - (d) Pocket field set for whole blood. This consists of six 1 oz. bottles to hold solutions of gravities covering the range 1.040-1.070 at intervals of 0.006. It serves to estimate blood gravities within ±0.002.
6. Apparatus for preparing the copper sulfate solutions: One volumetric flask of 100 ml. capacity and 1 buret, preferably also of 100 ml. capacity, for preparing standard copper sulfate solutions to be stored in 4 oz. bottles. If 2 oz. bottles are used, the flask and buret should be of 50 ml. capacity; if 1 oz. bottles

are used, the flask and buret should be of 25 ml. capacity.

7. Three 4 L. bottles.
8. 1 L. volumetric flask.
9. 500 ml. graduated cylinder.
10. 8 in. funnel and cotton or filter paper.
11. Thermometer, Centigrade, for liquids at room temperature.

Reagents:

1. Oxalate mixture (3:2 ammonium-potassium oxalate), 2%.
   (a) Dissolve 3 gm. ammonium oxalate and 2 gm. potassium oxalate in 250 ml. distilled water. This oxalate mixture, suggested by Heller and Paul, disturbs cell and plasma gravities less than either potassium or ammonium oxalate alone.
2. Crystalline copper sulfate, $CuSO_4 \cdot 5H_2O$. This is preferably purchased in the form of "fine crystals." Otherwise it must be pulverized before using. Four pounds provide a complete set (70) of 100 ml. standard solutions. Ten pounds will probably suffice a laboratory a year.
3. Stock copper sulfate solution of gravity 1.1000. *By weight:* If pure copper sulfate ($CuSO_4 \cdot 5H_2O$) can be weighed, this procedure is simpler than the saturation method.
   (a) Place in a dry 2 L. flask or bottle 170 gm. pure "fine crystals" of copper sulfate, weighed to within 0.1 gm.
   (b) Fill a 1 L. volumetric flask to the mark with distilled water and add, according to the temperature of the water, from a graduated pipet to the liter in the flask, sufficient additional water to bring the volume up to that indicated in the second column of Table 228A. Empty and drain the water from the flask into the bottle with the copper sulfate crystals. Stopper and rotate until all the crystals have dissolved. Then pour the solution once to and from the 1 L. flask to mix the solution within the water left adherent in that flask.
   (c) Or place in a 500 ml. flask or bottle 42.50 gm. copper sulfate, weighed within 0.02 gm.
   (d) Measure with a 250 ml. volumetric flask and a graduated pipet the volume of water indicated in the last column of Table 228A.
   (e) Dissolve and pour the solution back and forth as directed above.

For accuracy in this procedure, it is essential that the copper sulfate shall be pure and have the theoretical 5 molecules of water of crystallization. The crystals can be accurately analyzed by drying at 300°-350° in Pyrex weighing bottles samples of 2 or 3 gm. until the weight is constant, for which 2 or 3 hr. suffice. The theoretical loss of weight for the change from $CuSO_4 \cdot 5H_2O$ to anhydrous $CuSO_4$ is 36.06%. The analysis should be within 0.2% of this. The analyzed copper sulfate must be kept in tightly closed bottles until it is used to make the solution, or it may lose some of the water of crystallization to the air. Even after the 170 or 42.5 gm. portions of pure crystals have been weighed, they must be protected unless used at once; if they lost significant amounts of their crystal water the solution made according to Table 228A would have too little total water, and the gravity would be over 1.1000.

Table 228A. *Volume of water to add to 170 or 42.5 gm. $CuSO_4 \cdot 5H_2O$ to make stock solution of specific gravity 1.100*

Temperature of water (C. °)	*Ml. water to 170 gm. $CuSO_4 \cdot 5H_2O$*	*Ml. water to 42.5 gm. $CuSO_4 \cdot 5H_2O$*

From saturated copper sulfate solution.

4. Stock copper sulfate solution. Prepare 4 L. stock solution. The following directions will yield that amount.
   Saturation:
   (a) Provide 3 dry 4 L. bottles, a Centigrade thermometer for room temperatures, and an 8 in. funnel with a plug of cotton for rapid filtration. Fit the funnel to one of the bottles.
   (b) In another 4 L. bottle place 4 lb. "fine crystals" or pulverized crystalline copper sulfate and 2.5 L. distilled water. (Tap water of specific gravity not over 1.0003, compared with distilled water at the same temperature as 1.0000, may be used.)
   (c) Stopper the bottle and shake vigorously, with repeated inversions, for 5 consecutive minutes by the watch. (It is convenient to have 2 operators who shake during the alternate minutes.)
   (d) The instant the shaking is finished take the temperature to the nearest 0.5°. (It will be 2 or 3° cooler than the water before the saturation because the saturation process absorbs heat.)
   (e) After taking the temperature, immediately decant the solution off the crystals through the funnel with the cotton plug filter, to filter out suspended small crystals.
   (f) Dilute the solution at once to make the stock solution of gravity 1.1000.

Two and one-half liters of saturated solution suffice for more than 4 L. stock solution of gravity 1.100, and this in turn is sufficient for a complete set of 70 standard solutions of 100 ml. vol. each, with enough surplus to provide replacements for the standards that are most used. Smaller or larger amounts of the saturated solution can be made by using proportional amounts of copper sulfate and water.

Dilution:

(a) Measure the volume of saturated solution indicated in Table 228B into a 500 ml. graduated cylinder and pour into a 1 L. volumetric flask.
(b) Allow the upturned cylinder to drain into the flask for 30 sec.
(c) Fill the flask to the mark with water.
(d) Invert several times to mix the solution. The mixing results in a contraction, so that the meniscus now falls below the mark.
(e) Let the flask stand for 1 min. until the solution drains down from the neck.
(f) Add enough additional water to bring the volume to 1 L.

*Temperature in °C. refers to temperature of the saturated solution at the time of saturation (end of shaking for 5 min.)

(g) Mix and pour into a clean, dry, 4 L. bottle. Use the same 1 L. volumetric flask to prepare 3 more liters of the stock copper sulfate solution of gravity 1.100. Each time before the flask is used again, rinse it with water and discard the rinsings.

It is desirable that the saturated solution, the stock solution, and the standard solutions described below all be prepared at within 5° C. of the same temperature. The coefficients of expansion of the saturated and stock copper sulfate solutions are slightly greater than that of water, so that if, for example, the saturated and stock solutions were prepared at 35° C. and the standard solutions at 20°, the standard solutions would have more copper sulfate than intended, enough to make their gravities about 0.001 too high.

5. Standard copper sulfate solutions. In this method 4 oz. bottles are used to hold the standards.

Standard of 1.075 gravity:

(a) Measure 74.3 ml. stock solution of gravity 1.100 from a buret into a 100 ml. volumetric flask.
(b) Dilute to 100 ml. with distilled water and mix.
(c) Transfer to a labeled 4 oz. bottle and stopper to prevent evaporation.

Standard of gravity 1.074:

(a) Rinse the 100 ml. volumetric flask once with water and refill the buret from a 250 ml. Erlenmeyer flask containing the stock solution.
(b) Measure 73.3 ml. stock solution into the volumetric flask and dilute to 100 ml. with distilled water.

Standards of other specific gravities:

(a) Carry out the same procedure for preparation of the entire series down to 1.015, which covers the extreme ranges for blood and plasma. Use Table 228C to determine the amount of stock solution of gravity 1.100 to use.

Procedure for gravity analysis of blood and plasma: Do not apply the tourniquet for more than 1 min. when drawing whole blood. If desired, drops

*Plasma range—1.015-1.035.
Whole blood range—1.035-1.075.

of whole blood may be delivered directly into the standards from the syringe and needle. Or finger blood may be used. Prepare the finger puncture and take the blood up into a capillary tube. If the blood is transferred to a test tube containing anticoagulant, the cells and plasma must be thoroughly mixed immediately before a sample is drawn into a medicine dropper for the gravity test. For this purpose, (1) invert the tube 10 times or (2) raise and lower a glass rod with a mushroom end through the blood 10 times, just before the sample is drawn into the dropper.

Plasma gravity is best determined on plasma from blood that is treated with heparin, 0.2 mg./ml. blood as anticoagulant, since the heparin exerts no measurable effect on the gravity results. Or the Heller-Paul mixture of 3 parts of ammonium oxalate and 2 parts potassium oxalate may also be used for preparation of the blood. **Sodium citrate must not be used.**

Serum may be used in place of plasma. The gravity of serum indicates its protein content without the 0.2 or more gm. fibrinogen/100 ml. removed by the clotting.

Deliver the drop of serum, plasma, or whole blood from a height of about 1 cm. above the solution from a medicine dropper, syringe needle, or capillary tube. When the drop is delivered, steady the dropper on the edge of the bottle.

The delivered drop breaks through the surface

Approximate Hb percentage from G_B alone, stretch thread across G_B and mean normal G_P. Result on inner line.

Example. Line across chart shows calculation of Hb=100% (for men) from G_P=1.0264 and G_B=1.0595.

N.B. Plasma scales read up; others down.

Correction for oxalate, deduct from both G_B and G_P 0.0004 for each mg. 3:2 mixture NH_4 and K oxalates added per cc. blood.

Unit of sp. gravity is H_2O at same temperature.

Fig. 360. Line chart for calculating percentages of normal plasma proteins and hemoglobin from gravities of plasma and blood. (Courtesy U. S. Navy Research Unit, Hospital of the Rockefeller Institute for Medical Research, New York City, by permission of the Surgeon General, U. S. Navy; from Simmons, J. S., and Gentzkow, C. J., editors: Laboratory methods of the United States Army, ed. 5, Philadelphia, 1944, Lea & Febiger.)

film of the solution and then penetrates 2-3 cm. below the surface; within 5 sec. the momentum of the fall is lost and the drop then begins to rise, becomes stationary, or continues to fall. The gravity of the drop relative to the solution does not change appreciably until the drop has been immersed in the solution for another 10-15 sec., and there is ample time to note its behavior during this interval. **If the drop is lighter** than the test solution, it will rise, perhaps only a few mm., and may begin to sink immediately afterward. **If the drop is of the same gravity** as the standard test solution, it will become stationary for this interval and then fall. **If the drop is heavier,** it will continue to fall during this interval. It is to be emphasized that the behavior during the 10 sec. after the drop has lost momentum of its fall into the solution indicates whether the drop is lighter or heavier than the test solution—if it rises at all during this period, it is lighter than the standard.

For the test add a drop of the blood, serum, or plasma to various standards and select as the reading the standard that is of the same specific gravity as the blood, i.e., where the drop neither rises nor falls but remains stationary.

Calculation: Calculations are made with lined charts that take into account plasma protein concentration, hemoglobin concentration in blood, and

Fig. 361. Line chart for calculating plasma proteins, hemoglobin, and hematocrit from gravities of plasma and blood. (Courtesy U. S. Navy Research Unit, Hospital of the Rockefeller Institute for Medical Research, New York City, by permission of the Surgeon General, U. S. Navy; from Simmons, J. S., and Gentzkow, C. J., editors: Laboratory methods of the United States Army, ed. 5, Philadelphia, 1944, Lea & Febiger.)

hematocrit percentages. Hemoglobin and hematocrit values are estimated by laying a straightedge across the charts. See Figs. 360 and 361.

Accuracy of method: The hemoglobin content by the gravity method has been found regularly within 2% of the correct value measured by oxygen capacity. Usually the accuracy is within ±0.2 gm. In pathologic blood conditions, such as pernicious anemia, the error can be larger.

This method has been used widely in official circles and has been definitely accepted.

METHODS FOR STANDARDIZATION OF ROUTINE CLINICAL HEMOGLOBINOMETRY

The following 2 methods can be used for standardization of the routine methods discussed in the preceding pages.

Methods of hemoglobin determinations based on gasometric analysis

These determinations are performed in the Van Slyke-Neill apparatus. The methods were originally based on the oxygen capacity of blood. Various refinements, including the determination of carbon monoxide of the blood, have been added to the original method.[96] The method has a high degree of accuracy, but the procedure is too cumbersome for routine testing.

Even with this highly refined method, there remain some questions concerning normal values of human hemoglobin. In the past, it was assumed that the constant for oxygen combining with each gm. hemoglobin (**Hüfner factor**) was 1.34 vol.%. These data were based on observations on ox and horse blood.

$$\text{Gm. Hb/100 ml. blood} = \frac{20.9}{1.34} = 15.58$$

Each gm. oxyhemoglobin combines with 1.34 vol.% oxygen. In order to determine the number of gm. hemoglobin in 100 ml. blood, the oxygen capacity of blood is determined, and the vol.% O_2 in 100 ml. blood is divided by 1.34. The oxygen-binding capacity of 100 ml. blood is normally 20.9 vol.%.

Oxygen capacity measures only oxyhemoglobin and does not include hemoglobins which do not combine with oxygen, for instance, COHb, methemoglobin, and sulfhemoglobin.

Determination of oxygen content and capacity

A macromethod that makes use of the Van Slyke manometric apparatus and a micromethod using the Natelson microgasometer are described. The design and general instructions for the use of the instruments are given in the clinical chemistry section of this text and will not be repeated here.

The principle of the methods is identical. Blood is reacted with ferricyanide which oxidizes the hemoglobin to methemoglobin. This reaction is carried out in a partial vacuum in the chamber of the apparatus and results in the liberation of the oxygen which was combined with the hemoglobin and of gases dissolved in blood. The pressure of the gases liberated is measured and recorded; then an alkaline hyposulfite reagent which absorbs the oxygen is introduced into the chamber. A second pressure measurement is made, and the difference in these 2 pressure measurements then represents the pressure of the oxygen liberated.

This procedure differs from many described in that an alkaline rather than acid ferricyanide reagent is used which results in the liberation of oxygen quantitatively without the liberation of any carbon dioxide.

Reagents:

1. Ferricyanide-borate-saponin solution.

   Dissolve 1.6 gm. potassium ferricyanide, 0.5 gm. saponin, and 3 gm. sodium tetraborate decahydrate in distilled water and dilute to a total volume of 100 ml.

When used in the macroprocedure, this reagent is deaerated in the apparatus as part of the procedure, but when used in the microprocedure, it must be deaerated before introduction into the chamber. This may be accomplished very simply by placing the reagent in a bottle, covering it with a layer of mineral oil, and evacuating the bottle with a water aspirator or a vacuum pump. The layer of oil permits the escape of air bubbles from the solution but limits the diffusion of air back into it. This reagent is stable for approximately 2 wk. and in contrast to other reagents used in microgasometer technics should not be stored in contact with mercury.

2. Alkaline hyposulfite reagent.

   Place 2 gm. sodium hyposulfite ($Na_2S_2O_2$) in a small bottle or vial. Add 10 ml. 2N sodium hydroxide. Quickly dissolve the salt and cover with a layer of mineral oil. Deaerate as described for the ferricyanide reagent. This reagent is best prepared on the day of its use.

3. Caprylic alcohol.

Collection of sample: The sample is heparinized blood. When the oxygen content is to be determined, arterial blood is preferable since the results are more readily interpretable. Capillary blood, which is largely arterial, may be substituted, but usually yields values approximately 5% lower than arterial blood. There may be instances in which results obtained with capillary blood are not strictly comparable to those obtained with arterial blood. Blood for oxygen content must be drawn in such a way that exposure to air is excluded, and prior to analysis it should be stored under a layer of mineral oil. If only oxygen capacity is to be determined, then the source of blood is immaterial, and obviously the precautions concerning exposure to air do not apply.

1. Draw blood into a syringe which has been wet with a solution of heparin.
2. Plug the needle with a rubber stopper and mix the blood by rotation of the syringe.
3. Remove the stopper and express a few drops of blood from the needle.
4. Transfer the blood to a tube under a layer of oil. Leave sufficient blood in the syringe and transfer this to a flask for aeration for the oxygen capacity determination.
5. Aeration of blood for the capacity measurement is easily accomplished by placing the blood in a flask, where it will be spread out in a thin layer.
6. Shake for 5-10 min.

Capillary blood should be collected in heparinized tubes of about 1.5 mm. bore. A sample of about 0.05 ml. content can be transferred to a small tube under oil. The sample for oxygen capacity can be transferred to the bottom of a tube of about 10 mm. diameter and aerated by flicking the tube for about 3 min.

Procedure for Van Slyke apparatus

For 2 ml. blood:

1. Place 10 ml. ferricyanide reagent in the cup above the chamber and run into the chamber.
2. Draw 2 drops caprylic alcohol into the chamber, seal the top stopcock, and draw the level of mercury down just into the arm below the the chamber in order to minimize the surface of mercury in contact with the reagent.
3. Shake 3 min. to extract the air in the reagent.
4. Eject the extracted air from the chamber and force 6 ml. ferricyanide reagent up into the cup.
5. As quickly as possible after the solution has been run up into the cup, run the blood sample into the chamber of the apparatus. It is convenient for this purpose to use pipets which are graduated between the marks and which are fitted with a rubber tip.
6. Run 1 ml. reagent in the cup into the chamber after the blood sample, leaving 5 ml. in the cup.
7. Seal the top stopcock with mercury, aspirate the excess reagent from the cup, and rinse the cup with distilled water.
8. Again draw the mercury level down just below the chamber and extract the oxygen in the solution by shaking 3 min.
9. When the extraction is completed, bring the meniscus of the solution in the chamber to the 2 ml. mark and read p_1 from the manometer. This pressure is the resultant of the oxygen and nitrogen extracted from the blood.
10. To absorb the oxygen, lower the level of liquid in the chamber until the vol. of the space above it is approximately 5 ml., then close the stopcock to the mercury bulb.
11. Add 1.5 ml. air-free hyposulfite solution to the cup and admit this reagent to the chamber 1 drop at a time. As the reagent is added, it absorbs oxygen, and the level of mercury in the manometer falls. After the addition of several drops of reagent, no further perceptible fall of mercury in the manometer will occur.
12. When this point is reached, open the stopcock to the mercury bulb and permit the level of the solution to flow up in the chamber until it stops. The mercury bulb should be in its lower position when this operation is carried out. Now permit the remainder of the hyposulfite reagent to flow into the chamber and seal the top stopcock with mercury.
13. Allow a total of at least 4 min. to elapse after the first addition of hyposulfite, then bring the meniscus of the solution to the 2 ml. mark, and read P_2 from the manometer.
14. The oxygen pressure pO_2 is $p_1 - p_2$.
15. Record the temperature in the jacket of the extraction chamber.
16. Multiply the pO_2 by the proper factor from Table 229 to calculate the oxygen content in vol.% or mM/L.

Table 229. *Factors for calculation of O_2 content of blood (Van Slyke apparatus)*

31	0.2358	0.1181	0.1052	0.0527
32	0.2350	0.1177	0.1048	0.0525
33	0.2342	0.1173	0.1044	0.0524
34	0.2333	0.1169	0.1041	0.0522

For 1 ml. blood: The technic is the same as described for 2 ml. except that less ferricyanide is used; 7.5 ml. of the ferricyanide solution are first freed of air by 3 min. shaking, then 6 ml. are returned to the cup, and 1 ml. is returned with the blood sample to the chamber so that the final mixture is 1 ml. blood plus 2.5 ml. ferricyanide reagent.

Note: The oxygen content as determined represents both the oxygen bound to hemoglobin and the oxygen which is physically dissolved in the blood. In circulating arterial blood the correction for dissolved oxygen is quite small and approximates 0.25 vol.%.

However, when blood is saturated with air for the determination of its oxygen capacity, then the amount of oxygen dissolved varies with the temperature and with atmospheric pressure and reaches significant levels. When the oxygen capacity measurement is used to calculate the hemoglobin concentration, it then becomes imperative that the oxygen as determined be corrected for this dissolved oxygen. When blood is saturated with air at 25° C. and 760 mm. pressure, the physically dissolved oxygen is 0.62 vol.%. This value changes with atmospheric pressure to only a small extent, the magnitude of change being approximately 0.02 vol.% for each 20 mm. change in pressure; the dissolved oxygen increases with increasing pressure and vice versa. The dissolved oxygen increases as the temperature falls and vice versa; the magnitude of this change is approximately 0.017 vol.% per degree.

To calculate the hemoglobin concentration of a blood sample, the oxygen content in vol.% air-saturated blood is corrected for the dissolved oxygen, and the corrected value is multiplied by 0.746 to give gm.% hemoglobin. This factor is derived from the observations that 1 gm. adult human hemoglobin combines with 1.34 ml. oxygen (1 gm.% Hb = [oxygen capacity in vol.% − dissolved oxygen in vol.%] × 0.746).

Another important parameter which can be calculated from the determination of both the oxygen content and capacity of a blood sample is its degree of saturation with oxygen. The **oxygen saturation** is calculated as follows:

$$\%\ \text{Oxygen saturation} = 100 \times \frac{\text{Vol.\% } O_2 \text{ bound by Hb in blood as drawn}}{\text{Vol.\% } O_2 \text{ bound by Hb in saturated blood}}$$

Procedure for Natelson microgasometer

Reagents: The reagents are as described for the Van Slyke procedure. Note the precaution with regard to the ferricyanide reagent that it must be deaerated before it is introduced into the chamber and preferably only shortly before its use.

Procedure:

1. Draw up 0.03 ml. blood, followed by a 0.1 ml. mercury plug.
2. Draw up 0.02 ml. caprylic alcohol, 0.03 ml. ferricyanide reagent, 0.02 ml. caprylic alcohol, and 0.03 ml. ferricyanide reagent in that order and follow with mercury until all the reagents are beyond the stopcock.
3. Close the stopcock and retreat with the plunger until all the reagents are drawn into the lower portion of the bulb.
4. Shake for 3 min.
5. Bring the meniscus to the 0.12 ml. mark and take a reading on the manometer.
6. Retreat again until the reagents are in the lower portion of the bulb and shake for 2 min.
7. Advance the meniscus to the 0.12 ml. mark and take a second reading.
8. When 2 consecutive readings agree, all of the oxygen is liberated, and this manometer reading is p_1.
9. Advance the screw so that the mercury in the manometer barely reaches the top and open the stopcock.
10. Advance the screw until a drop of mercury protrudes from the tip of the pipet.
11. Draw up 0.03 ml. hyposulfite reagent and follow with mercury until the reagent is beyond the stopcock.
12. Close the stopcock.
13. Retreat with the plunger until the reagents are in the lower part of the bulb.
14. Shake 3 min. to absorb the oxygen, bring the meniscus of the solution to the 0.12 ml. mark, and read the pressure in the manometer. This is p_2.

Calculations:

Oxygen in vol.% = $(p_1 - p_2)$ × factor from Table 230.

Oxygen in mM/L. = Vol.% × 0.446

Gas chromatography

Gas chromatography allows analysis of whole blood for oxygen, nitrogen, and carbon dioxide contents in just a few minutes. Fisher's clinical gas partitioner* requires 0.1 ml. blood for complete gas analysis and measures content or capacity. Gas chromatography uses the established technic of column chromatography. In gas chromatography an inert carrier gas dilutes the gaseous specimen and carries it through chromatographic columns at different speeds as molecules of different gases interact with the packing material to different degrees. This interaction may consist of adsorption on the packing material. The different components consequently separate and are eluted from the columns at different times.

Methods of hemoglobin determinations based on measurement of iron content of blood

Basically, the many modifications for determining iron content of blood depend upon liberation of the 4 iron molecules attached to the 1 globin molecule in hemoglobin. The Wong method (p. 229) is a typical technic. The subject of iron determination in blood has been very thoroughly covered in a symposium on hemoglobinometry.[97] The iron method is too cumbersome for routine clinical work, but its accuracy (±1%) has made it a popular method for the calibration of clinical methods. If whole blood is used for the iron determination, the result must be corrected for the plasma iron. One gram hemoglobin contains 0.335 mg. iron.

*Fisher Scientific Co., New York, N. Y.

CRITIQUE OF HEMOGLOBINOMETRY

Determination of hemoglobin is perhaps one of the most common laboratory procedures in a hematologic study of patients; yet there exists more inaccuracy in this determination than in many other tests. The subject was of sufficient interest to warrant its presentation before the American Society of Clinical Pathologists and the College of American Pathologists in 1950. As a result, a most comprehensive monograph on clinical hemoglobinometry was published.[97] These authors stated: "Recent surveys have revealed wide discrepancies in hemoglobin measurements in different clinical laboratories. These are in part due to errors in measurements, differences in methodology, the uncertainties encountered with the continuance of obsolete color methods that use artificial standards, and, perhaps most important, because of a lack of an accepted standard of reference for hemoglobinometry."*

Karr and Clark[98] call attention to inaccurately calibrated pipets, both for blood sampling and for measuring diluents, as a source of error. They also include careless technic as an important factor in poor results. For accurate hemoglobin determination, all equipment used must be calibrated and standardized. If it is impossible to calibrate instruments because of lack of properly trained personnel, the work can be done either by experts in the vicinity or by supply houses which furnish such equipment. Once a photoelectric colorimeter has been calibrated, it should be checked from time to time for accuracy.

Regarding methodology, today we are solving one of the problems that has plagued us in hemoglobinometry for the past 80 yr. by the use of photoelectric colorimetry. Obviously such precision instruments have a considerable advantage over all methods utilizing visual colorimetry. However, the use of a precision instrument does not guarantee precise results unless all technical aspects in the use of the instruments are properly understood and carried out.

It would be exceedingly helpful if there could be some universal agreement as to the normal values for hemoglobin. Here in the United States, it is generally agreed that the average normal hemoglobin concentration for males is 15.8 gm./100 ml. blood, and for females, 13.9.[99] Since these figures represent accumulations of great numbers of observations, it is suggested that this be used as a standard for normals in the United States. From a clinical standpoint, it is important to remember that there are ranges of hemoglobin values that are still within the normal range for both males and females. Such ranges as given by Albritton are for adult males 14-18 gm./100 ml. blood and for adult females 11.5-16 gm./100 ml. Acceptance of these ranges of normal values must not be construed as placing a seal of approval on poor technic which results in variations perhaps on the same sample of blood.

The time-honored tradition of reporting values in percentage is so well established that it has been difficult in many places to discard this method of reporting. The time has now come when **reporting hemoglobin in percentages should be discontinued.** A most casual perusal of the various "normals" for 100% for the different instruments used in hemoglobinometry reveals great disparity between the number of gm. hemoglobin/100 ml. that equals 100%. In Table 231 are figures indicating some of the values considered 100% in various methods.

Table 231

Instrument	*Gm. Hb/100 ml. blood*
Sahli	13, 8, 14, 14.5, 17, 17.2, 17.3, etc.
Sahli-Leitz	15
Dare	13.75, 13.77, 13.8, 15.9, 16.9
Tallqvist	13.8, 15.6, 15.8, 16.25, 16.5
Newcomer	16.92
Haldane	13.8
Haden-Hausser	15.4, 15.6, 16.7
von Fleischl-Miescher	15.8
Van Slyke	16.9

To convert from % hemoglobin to gm. hemoglobin in 100 ml. blood, multiply the gm. standard of the apparatus used by the % hemoglobin as read on the hemoglobin scale.

To convert from gm. hemoglobin/100 ml. blood to % hemoglobin, divide the number of gm. in the patient's blood by the gm. standard of the apparatus and multiply by 100.

---

*From Sunderman, F. W., et al.: Am. J. Clin. Path. **23**:519, 1953.

The ultimate choice for hemoglobin determination should be related to the purpose for which determinations are made, with appreciation for the limits of accuracy of the method to be used. Generally speaking, the less expensive types of equipment with relatively simple technics might be chosen in situations in which screening is all that is desired. The Sahli, Haden-Hausser, Dare, and Spencer instruments fit into this category. These methods have shown errors ranging from ±5 to 40%, but "with a close check on the standards, it may be possible with careful technic to hold the error to ±5 to 10%."[97]

In clinical laboratories and hospitals and even in private offices of physicians, where a fair amount of hematology is performed daily, the cost of a well-standardized photoelectric colorimeter is not so prohibitive as to preclude its use routinely. In modest-sized hospital laboratories and in physicians' offices, it is recommended that the photoelectric colorimeter be of such construction as to permit its use for multiple determinations as well as of hemoglobin. Purchase of a photoelectric colorimeter which has been standardized for hemoglobin determinations only and which has the convenience of reading the concentration of hemoglobin directly from the ammeter on the instrument is not economical in the smaller laboratory. In large laboratories where several photoelectric colorimeters are available and where the use of one could be limited to determinations of hemoglobin, perhaps there may be some justification for the purchase of an instrument calibrated for hemoglobin only. Regardless of which type of photoelectric instrument is purchased, attention is again called to the fact that a **paramount prerequisite of its use is accurate calibration.** The fact that a hemoglobin determination has been performed with a photoelectric apparatus is no guarantee that it is accurate. This precision is directly proportional to the accuracy of calibration of the instrument, as well as to precision in the performance of the technic.

One satisfactory method for the clinical laboratory using photoelectric colorimetry is the Sheard-Sanford technic or some modification of it in which oxyhemoglobin is measured. Accuracy in this method is somewhere in the range of ±4%. Sunderman et al. stated: "It is the considered opinion of members of this panel that for routine clinical use, the carboxyhemoglobin methods, the cyanmethemoglobin methods, and the oxyhemoglobin colorimetric methods (in the order named) are the most reliable and trustworthy."* The use of poisonous cyanide reagents in the cyanmethemoglobin method is a major objection to this method. Our objection to the carbon monoxyhemoglobin methods is the introduction of a complicating element (a tank of carbon monoxide or a source of illuminating gas) that is hardly justified for routine clinical procedures. This choice of oxyhemoglobin method is made with a full realization that it does not measure hemoglobin derivatives such as carboxyhemoglobin, methemoglobin, and sulfhemoglobin.

The gasometric methods are obviously unsuited for clinical hemoglobinometry, requiring special equipment and being time-consuming. The precision of such methods favors their use in the calibration of photoelectric instruments. However, many prefer methods based on iron analyses (accuracy ±1%) for calibration. These methods are likewise too cumbersome for routine clinical work.

In the calculation of erythrocyte constants (mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration), the hemoglobin determinations must be based on methods having a high degree of accuracy.

DETERMINATION OF ABNORMAL HEMOGLOBINS BY ELECTROPHORESIS

Abnormal hemoglobins may be demonstrated in the Tiselius apparatus. This equipment is expensive, and procedures are laborious. A substitute for this apparatus has been found in the form of paper electrophoresis outfits.

The basic principle of the method is the observation of the migration of a drop of protein (stained or unstained) on a piece of filter paper moistened with buffer solution in an electrophoresis hookup.[100-103]

The various hemoglobins detected by electrophoresis are known as hemoglobins A (normal adult), F (fetal), C, D, E, G, H, I, and S (sickle cell). Descriptions of the significance of these varieties of hemoglobin may be found in the discussion of hemoglobinopathies. The relative mobilities of these hemoglobins have the following order: A, F, E, S, D, and C. The apparatus is described in the discussion of electrophoresis.

*From Sunderman, F. W., et al.: Am. J. Clin. Path. 23:519, 1953.

ALKALI DENATURATION TEST FOR FETAL HEMOGLOBIN (HEMOGLOBIN-F)*

Material:

1. 2 to 4 ml. of oxalated venous blood.
2. N/12 Potassium hydroxide.
   Dilute 1 part N/4 potassium hydroxide solution with 2 parts distilled water. Keep the stock solution in a refrigerator in tightly stoppered paraffin-lined bottle.
3. Precipitating reagent.
   Add 400 ml. distilled water and 2 ml. concentrated hydrochloric acid (10N) to 400 ml. saturated solution of ammonium sulfate.
4. Conical graduated centrifuge tubes.
5. Toluene, c.p.
6. Physiologic saline, 0.85%.
7. Stopwatch.
8. Photoelectric colorimeter.

Procedure:

1. Place the blood in a 15 ml. conical centrifuge tube.
2. Wash once with saline solution, centrifuge, and discard washings.
3. Add 1.5 vol. distilled water and 0.4 vol. toluene.
4. Stopper and shake vigorously for 2-3 min. and allow to stand overnight in a refrigerator at about 4°-10° C. If it is desirable to proceed immediately, then shake for 5-6 min. and continue without refrigeration.
5. Centrifuge for 20 min. at 2000-5000 r.p.m.
6. Aspirate and discard upper clear layer and middle layer of sediment.
7. Filter the hemoglobin solution remaining in the centrifuge tube. The concentration of this hemoglobin solution will be between 8 and 12 gm.% and need not be checked.
8. Transfer 1.6 ml. N/12 potassium hydroxide solution to a Kahn tube and keep in a 20° C. water bath for several min.
9. Add 0.1 ml. test solution of hemoglobin to the precipitating reagent, rinsing the pipet 6 times and agitating the tube gently 10-20 times. As soon as the hemoglobin solution has been added, time with the stopwatch.
10. At the end of exactly 1 min., add 3.4 ml. precipitating reagent of ammonium sulfate.
11. Stopper, invert 3-4 times, and filter into a clean tube (**solution A**).
12. Determine the hemoglobin concentration of solution A in a photoelectric colorimeter.
13. Prepare a 1:200 dilution original hemoglobin solution by adding 0.02 ml. (with a Sahli pipet) to 4 ml. distilled water (**solution B**).
14. Determine the hemoglobin concentration of solution B in a photoelectric colorimeter.

Calculations:

$$\%\ \text{fetal hemoglobin} = \frac{\text{Hb concentration sol. A} \times \frac{1}{4}}{\text{Hb. concentration sol. B}} \times 100$$

The factor ¼ is used to compensate for differences in dilutions of solutions A and B, which are 1:50 and 1:200, respectively.

Normal (hemoglobin-F):

Newborn infants	55-85%
12 to 18 mo.	0-10%
1½ to 5 yr.	0- 3%
Over 5 yr.	0- 1.8%

Comments: For routine clinical studies, visual observation only of solution A may suffice since concentrations of 2% or more of hemoglobin-F will impart a brownish or red color to the filtrate. Concentrations below 2% hemoglobin-F result in colorless solutions. Diagnostically, values above 2% are significant and therefore this qualitative determination alone may be all the procedure necessary.

Attention is directed to the high concentrations (55-85%) of hemoglobin-F in newborn infants and the existence of elevated concentrations of this hemoglobin component generally up to 2 yr. of age. Occasionally, children up to 5 yr. of age may show slightly increased values (up to 3 or 4%). Allowance should be made for these ranges in the study of disease under these conditions.

Elevations of alkali-resistant hemoglobin-F occur almost constantly in the hereditary hemolytic syndromes. In thalassemia, concentrations up to 90% hemoglobin-F have been found, whereas in sickle cell anemia the concentration may reach 25%. In hereditary spherocytosis, levels up to 20% hemoglobin-F are not unusual. The levels reached in a particular patient do not necessarily distinguish these various syndromes from one another.

The finding of moderate increases of fetal hemoglobin is not necessarily diagnostic of familial or hereditary hemolytic disease. Values up to 5 or 10% have been found in chronic leukemia, multiple myeloma, and pernicious anemia. In almost all other anemias, such as iron-deficiency anemia and acquired hemolytic anemias, hemoglobin-F concentrations are normal.

VOLUME PER CENT OF ERYTHROCYTES (CELL VOLUME PER CENT OR HEMATOCRIT)

Measurement of the volume of packed red blood cells/100 ml. blood by the hematocrit technic is the most accurate and simplest method of determining the presence or absence of anemia or polycythemia and of measuring their degree. In comparison, hemoglobin determination is less accurate, and red blood cell counting is far less accurate.

---

*Submitted by Dr. A. I. Chernoff as modification technic of Singer et al.[104]

Relative to these determinations Wintrobe,[105] in a personal communication, stated: "It has been our practice for years to do just this and to reserve the determination of hemoglobin and red cell counts for those instances where one wishes to know what the average size and hemoglobin content of the red cells are. When this is needed, then the hemoglobin should be measured carefully, and the red cell counts should be carried out meticulously. Even then, red cell counting carries a substantial margin of error. Certainly, as red cell counting is done in ordinary practice, it carries an error of anywhere from 20 to 50% or more. I see many instances of erroneous blood cell counting and, strangely enough, most physicians are unaware of the large margin of error in this determination."*

The hematocrit determination made on venous blood is called venous hematocrit. It measures the relative amount of red cells in the plasma of the blood and thus measures the concentration of red blood cells. It does not measure the total blood volume. To determine the latter, other methods should be used or allowance should be made for the plasma trapped in the erythrocyte column. The latter can be measured with radioiodinated albumin or determined from a graph based on standardized methods of centrifugation. The total body hematocrit is roughly 9% higher than the venous hematocrit.

The hematocrit values form the basis of some of the blood constants and indices, which serve to characterize types of anemias.

In preoperative and postoperative hemorrhage, hematocrit examinations are useful in controlling blood replacement.

As just mentioned, the hematocrit technic is a useful method to determine the presence or absence of anemia or of polycythemia.

HEMATOCRIT[106]

Normal:

Adult male: average, 47 vol.%; range, 40-54.
Adult female: average, 42 vol.%; range, 37-47.

Macromethod for hematocrit determination—Wintrobe

Equipment:

1. Wintrobe hematocrit tube.

   This is a heavy cylindrical tube marked off on the exterior on the left-hand column from 0-10 cm. and on the right from 10-0, beginning at the top of the tube. Each main division represents 1 cm. and each small division 1 mm. To convert the reading to percentage when the tube has been filled to the top, multiply the figure in cm. by 10 or read directly in mm.

   Collect blood by venipuncture, place in 3:2 oxalate mixture (p. 1100), and mix thoroughly but gently.
2. Hematocrit-filling pipet.

   These are long glass capillary pipets or preferably metal cannulae which fit inside the Wintrobe tube. Disposable long pipets are especially useful for this purpose.
3. Centrifuge.

   This should be capable of a speed of 3000 r.p.m. or 2000 g. The type of centrifuge is important since a standardized reproducible method requires a constant centrifugal force which in turn depends on the radius and the speed of the centrifuge and the direction of the centrifugation. In the routine clinical laboratory, absolute packing of the red cells usually cannot be achieved since a centrifugal force of about 200,000 g is required. The test is reproducible if a standard time and a standard centrifugal force are used.

Procedure:

1. Mix the oxalated venous blood thoroughly.
2. Draw up sufficient blood to fill a Wintrobe tube, slightly more than 1 ml. in a dry filling pipet.
3. Insert the tip of the pipet to the bottom of a clean dry Wintrobe hematocrit tube. By gentle pressure of the rubber bulb at the end of the pipet, fill the hematocrit tube, slowly pulling up on the pipet. Avoid introducing air bubbles. The tube should be filled to exactly the **0** on the left side of the tube. If the tube is filled beyond this point, remove enough blood so that the meniscus is at exactly **0** point. If insufficient blood is available for filling the entire hematocrit tube, the tube may be filled to any mark and the vol.% packed erythrocytes calculated by dividing the volume of packed erythrocytes by the total volume of blood in the tube. If the tube is filled to exactly to **0** mark, readings can be taken directly from the tube.
4. Close the open end of the tube with a small rubber stopper supplied with the apparatus to prevent evaporation. This is not necessary if the tube has been filled to the **0** mark. If less than this amount of blood is used, the open end of the tube must be closed to prevent evaporation during centrifugation.
5. At this point if desired, the Wintrobe tube may be placed in a rack or in an upright position and allowed to stand for 1 hr. to determine the sedimentation rate and then centrifuged for the hematocrit determination. If the sedimentation rate is not desired, centrifuge for 30 min. at 3000 r.p.m.
6. Read the volume of packed red blood cells directly on the tube at the meniscus of the erythrocyte column. Read from the bottom up and multiply the reading on the right side (cm.) of the tube by 10 to obtain the vol.% of packed erythrocytes.

---

*From Wintrobe, A. A.: Personal communication.

Examine the hematocrit tube for other features. Beginning at the top of the tube, observe the **fatty layer,** which is normally barely visible. When the blood fat content is exceedingly high, a layer of several ml. may be seen at the top of the tube. The main column in the tube from the top down is plasma. Normally, this **plasma layer** is a pale straw-colored yellow and is fairly clear. A cherry-red color is evidence of excessive hemolysis. Hemolysis may be due to faulty technic, such as collection of blood in wet syringes or wet needles or placing it in a wet hematocrit tube. Hemolysis may also occur as a result of exposure of the blood to high temperatures (radiators) before the determination is made or as a result of some inherent disease of the red blood cells. In the presence of excessive hemolysis, the hematocrit values will be abnormally low and, therefore, incorrect. In such cases, a new blood specimen should be obtained, and all precautions should be taken to prevent hemolysis.

The plasma may also be tinted a deep yellow or almost brown color, indicating the presence of jaundice. The intensity of this color is an indication of the intensity of the jaundice.

Just beneath the plasma layer is a reddish gray layer or **buffy coat,** which normally varies in thickness from 0.5-1 mm. This layer consists of packed leukocytes and platelets, the thickness of the layer roughly representing the total counts of leukocytes and platelets. If this layer is exceedingly thin, e.g., less than 0.5 mm., it may indicate a reduction in platelets or in leukocytes. If it is greater than 1 mm., it usually represents an increase in the leukocyte count above 10,000/c.mm. Sometimes this layer may subdivide into 2 indistinctly separated layers, of which the uppermost portion is rich in platelets and the lower almost exclusively leukocytes. In marked leukopenia, the leukocyte layer may be aspirated and spreads made for differential counting in order to obtain a greater concentration of white cells. This is not recommended as a routine procedure because white cells collected in any anticoagulant show morphologic changes sufficiently great to give a wrong impression of the true character of these cells.

In searching for **lupus erythematosus (L.E.) cells,** the buffy coat of the hematocrit tube serves as a very useful concentration method.

Permit the blood specimen to remain at room temperature for approximately 2 hr. before centrifugation if the preparation is to be examined for L.E. cells.

Some workers who collect **bone marrow** preparations in an anticoagulant use the hematocrit tube method as a rough estimate of the relative cellularity of the bone marrow. Various figures are given for the normal thickness of the buffy coat of bone marrow, ranging from 5-10 mm. This crude method is not a true gauge of the cellularity of the bone marrow, varying considerably with the technic of the operator who performs the aspiration and with the amount of bone marrow removed.

In the event that less than 1 ml. blood is available, the hematocrit determination made with this lesser quantity is calculated as follows.

Suppose that the hematocrit tube has been filled to the 6 mark (60 mm.). The vol. packed red cells after 30 min. centrifugation is at the 2.4 mark (24 mm.).

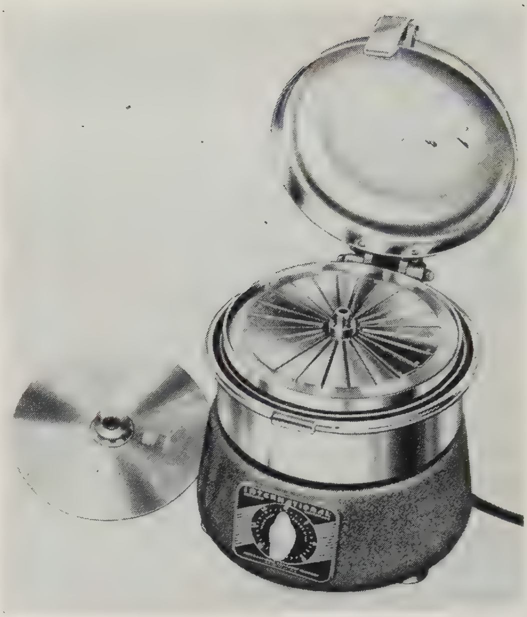

Fig. 362. International microhematocrit centrifuge, showing special hematocrit head, cover, and automatic timing device. (Courtesy International Equipment Co., Boston, Mass.)

$$\text{Vol. packed red blood cells } (\%) = \frac{24}{60} \times 100 = 40\%$$

Microtechnic for hematocrit determination

Equipment:

1. Capillary tubes (heparinized).
2. High-speed centrifuge.
   The Guest-Weichselbaum* centrifuge is excellent. This centrifuge is made with a motor which has a speed of 10,000 r.p.m., and an automatic electric timer built into the apparatus. The special flat head contains notches which permit handling 24 microhematocrit determinations simultaneously. A flush-fitting cover, held in place by a set screw, is furnished with the centrifuge. (Fig. 362.)
3. Plastic hematocrit linear scale for direct reading (Fig. 364).

Procedure:

1. If oxalated venous blood is available, fill the open end of a **plain** capillary tube with blood. If capillary blood is used, fill a **heparinized** capillary tube with the blood sample.
2. Seal the ends of the tube with a lighted match or a burner. Other sealing methods are available, such as rubber cups and special sealing wax.
3. Place the capillary in the centrifuge, the sealed end toward the outside, taking care to balance it against another tube of the same

---

*Aloe Scientific, St. Louis, Mo.

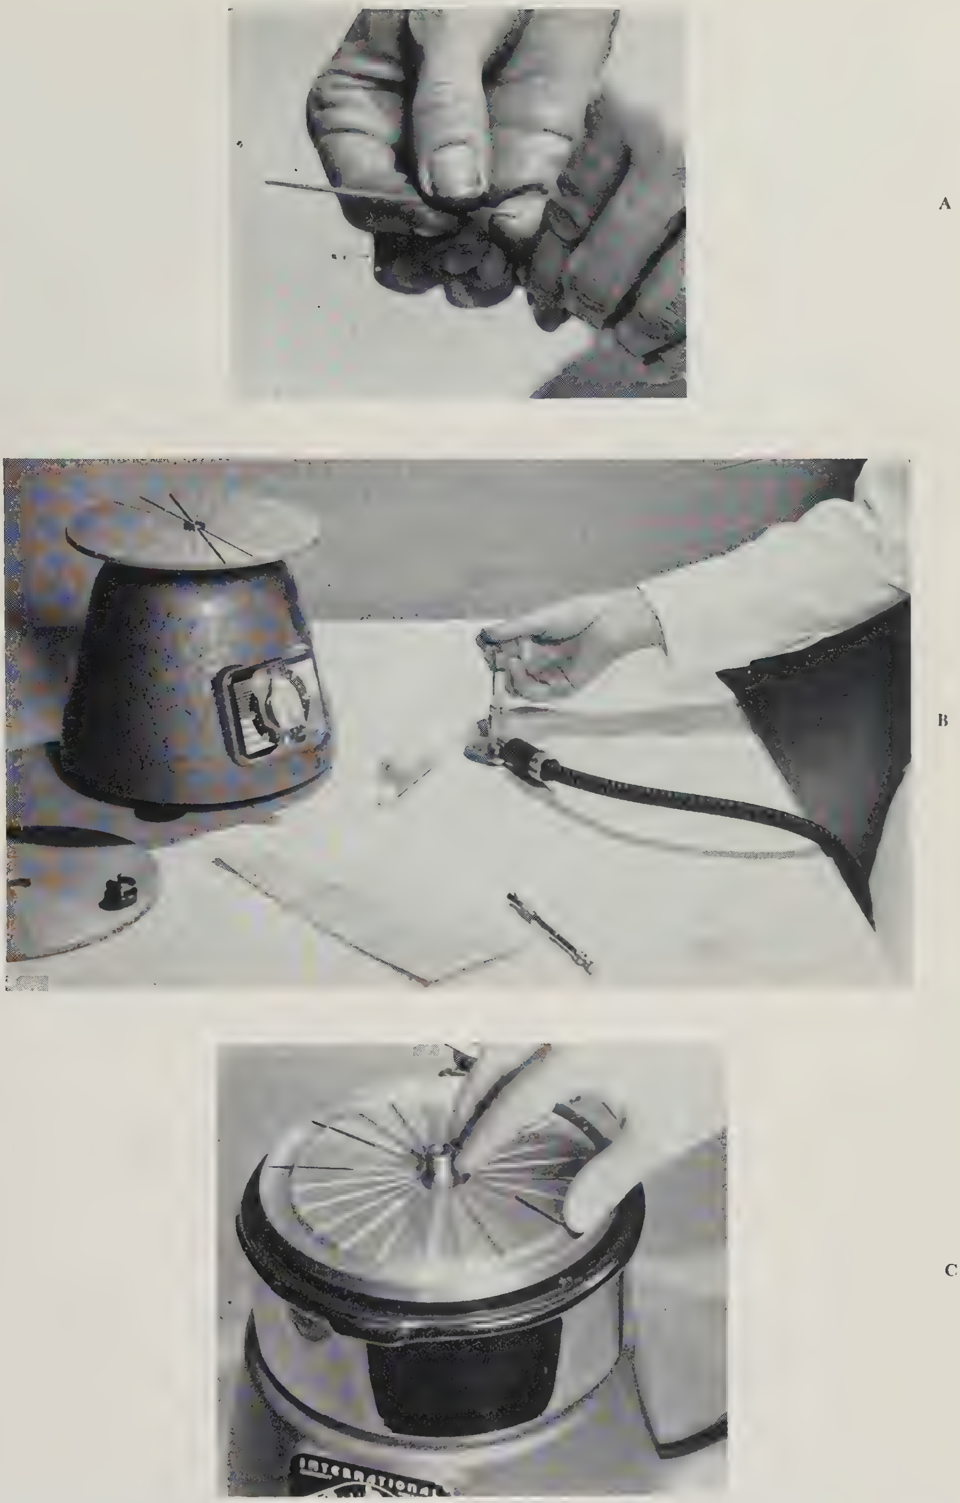

Fig. 363. A, Obtaining finger blood for microhematocrit test. The blood is taken in a capillary tube containing an anticoagulant. **B,** Sealing capillary containing blood preparatory to centrifuging in special hematocrit-head centrifuge. **C,** Placing sealed capillary in special centrifuge head for microhematocrit test. Tubes must be placed opposite each other for balancing centrifuge head. (**A** and **B,** courtesy Aloe Scientific, St. Louis, Mo.; **C,** courtesy International Equipment Co., Boston, Mass.)

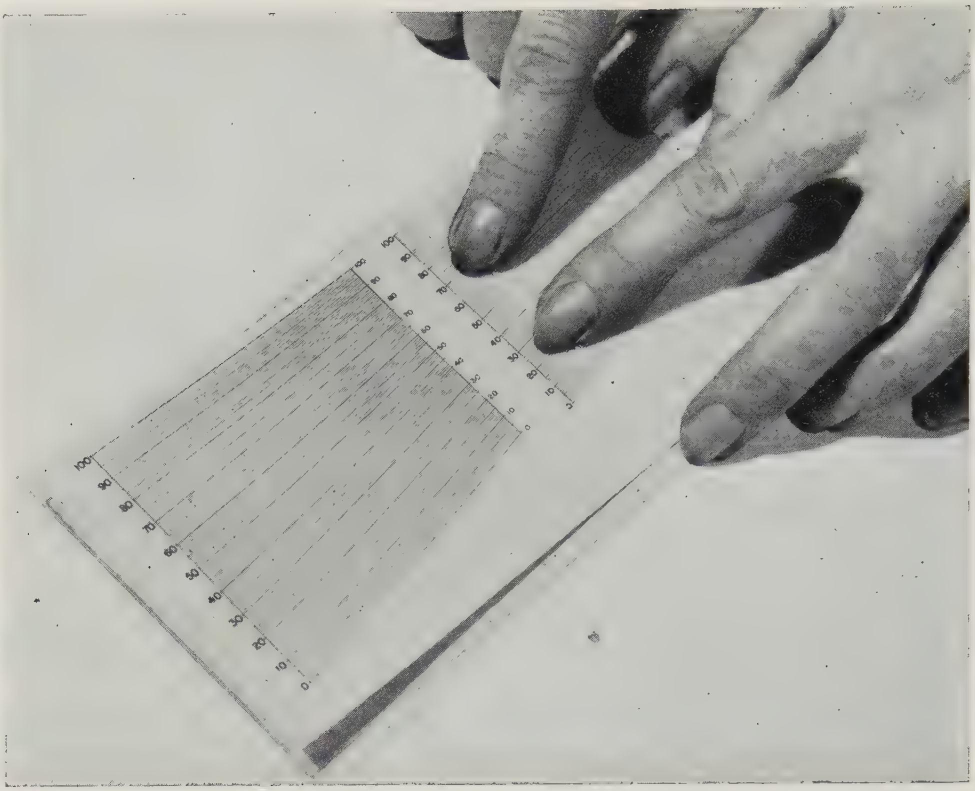

Fig. 364. Special plastic hematocrit linear scale for reading cell vol.% of erythrocytes in microhematocrit test. Capillary tube is placed on scale with bottom of blood column on "0" line and top of column of blood at "100" line. Read the volume of packed cells from scale at left of graphic reader. (Courtesy Aloe Scientific, St. Louis, Mo.)

size on the opposite side of the centrifuge head.

4. Place the cover on the centrifuge and centrifuge, setting the automatic timer at 4 min.
5. Read % blood cell vol. directly from the graphic reader. Hold the tube against the linear chart so that the top of the liquid is exactly at the top line and the bottom of the tube agaisnt the bottom line. Move the tube until it reaches such position and then read vol. packed cells directly from the reader.
6. With a magnifying hand lens, examine the characteristics of the plasma and those of the buffy coat of platelets and leukocytes.

Comment: The advantage of this micromethod is that it requires small quantities of blood and therefore lends itself well to pediatric practice. In emergency situations such as those associated with blood loss and shock, the short centrifuging time offers a distinct advantage over the macrotechnic. Another advantage is that the capillary tubes are inexpensive and disposable.

Interpretation: In anemias generally the hematocrit is reduced below the normal figures, i.e., below 40 vol.% in males and 37% in females. This method is therefore a very simple, readily available method for detecting the presence or absence of anemia. However, the hematocrit alone does not disclose the nature of the anemia and at times may fail to reveal an existing anemia although this is rarely the case.

In polycythemia, the hematocrit value is elevated above 54% in males and 47% in females. The degree of increase, however, does not indicate the nature of the polycythemia, failing to distinguish between polycythemia vera and secondary polycythemia.

In shock associated with surgery, trauma, and burns, hemoconcentration occurs and may be measured by increases in the hematocrit values (rapidly rising).

In conditions associated with hydremia, such as cardiac decompensation, pregnancy, excessive administration of fluids, and other similar states, the hematocrit values may be below normal, and yet no anemia may be present.

ERYTHROCYTE CONSTANTS AND INDICES

After the erythrocyte count, hemoglobin, and hematocrit values in a patient are determined, it is possible to express individual aspects of the red blood corpuscles in either the absolute terms of Wintrobe[107] or the older relative terms. The most commonly used constants are helpful in designating such characteristics of red blood cells as size and hemoglobin content and hemoglobin concentration. In order for these constants to have any real significance, the basic determinations of erythrocyte count, hemoglobin, and hematocrit must be performed accurately. Wintrobe recommends the use of absolute terms for these constants in contrast with the older terms which were relative and were based on percentages:

CONSTANTS RELATING TO ERYTHROCYTE SIZE

Mean corpuscular volume

The mean corpuscular volume (MCV) in cubic microns (cμ) is determined by the following formula:

$$\text{MCV} = \frac{\text{Vol. packed red cells, ml./1000 ml. blood}}{\text{Erythrocyte count millions/c.mm.}}$$

Normal:

Adult males: average 87 cμ; range, 70-94.

Adult females: average 87 cμ; range, 74-98.

Examples:

Normal blood: Hematocrit is 45 vol.%; erythrocyte count is 5,000,000.

$$\text{MCV} = \frac{45 \times 10}{5} = 90 \text{ c}\mu$$

Microcytic anemia: Hematocrit is 22.5; erythrocyte count is 3,500,000.

$$\text{MCV} = \frac{22.5 \times 10}{3.5} = 64 \text{ c}\mu$$

Macrocytic anemia: Hematocrit is 21.2; erythrocyte count is 2,000,000.

$$\text{MCV} = \frac{21.2 \times 10}{2.0} = 106 \text{ c}\mu$$

Volume index

This index corresponds to the mean corpuscular volume. It is determined by the following formula:

$$\text{Vol. index} = \frac{\%\text{ vol. packed erythrocytes}}{\%\text{ erythrocytes}}$$

Normal: Average, 1.0; range, 0.85-1.15.

It is customary to take an arbitrary figure, such as 43.2, for the normal hematocrit and 5,000,000 for the normal red blood cell count to represent 100% in these calculations. As with all such determinations, there is a difference of opinion as to what constitutes 100%. We suggest, for consistency, that the mean average levels given in Table 232 be taken for these determinations.

Table 232. *Mean average normal value of hematocrit and RBC count*

	Hematocrit	*Erythrocytes/ c.mm.*
Adult males	47 vol.%	5,400,000
Adult females	42 vol.%	4,800,000

Examples:

Normal female:

Hct., 40. 40 ÷ 42 is 95% of normal.

RBC, 4,500,000. 45 ÷ 48 is 94% of normal.

$$\text{Vol. index} = \frac{95}{94} = 1.01$$

Normal male:

Hct., 48. 48 ÷ 47 = 102% of normal.

RBC, 5,200,000. 52 ÷ 54 = 96% of normal.

$$\text{Vol. index} = \frac{102}{96} = 1.06$$

Microcytic anemia—male subject:

Hct., 22.5. 22.5 ÷ 47 = 48% of normal.

RBC, 3,500,000. 35 ÷ 54 = 65% of normal.

$$\text{Vol. index} = \frac{48}{65} = 0.74$$

Macrocytic anemia—female subject:

Hct., 21. 21 ÷ 42 = 50% of normal.

RBC, 2,000,000. 20 ÷ 48 = 42% of normal.

$$\text{Vol. index} = \frac{50}{42} = 1.18$$

Comments on determination of size of red blood cells

We recommend determination of the mean corpuscular volume over determination of volume index as an expression of the **mean** size of red blood cells. Certain reservations should be made, however, in accepting mean corpuscular volume figures as necessarily reflecting extreme accuracy. The accuracy of the mean corpuscular volume is only as great as the accuracy of the methods by which the red count and the hematocrit value have been determined.

There are many ways of determining the size of red cells. Perhaps the simplest is to examine a well-prepared blood spread, in which recognition of variations in size as well as the general trend in size is readily perceptible. The blood spread should be used as a check on mean corpuscular volume determinations.

There are other methods for determining the size of red blood cells, but generally speaking, these are of relatively little practical clinical value. Most of these are perhaps of greater historic interest than of practical value. Among the earliest attempts at the measurement of the actual diameter of red blood cells is the **method of Price-Jones,**[108] who made camera lucida drawings of red cells, measuring the actual diameters of the drawings of from 500 to 1000 cells. From these drawings, he constructed curves which are spoken of as the **Price-Jones curves,** showing the distribution of various cell sizes. These curves were so graphed that shifts to the left of the normal distribution curve were seen when the mean diameter of the red cells was diminished, and shifts to the right were seen when the mean diameter was increased.

Three main types of curves are described. The curve of the **normal blood** shows a peak at about 7.2μ. The diameter of red blood cells of **newborn** infants and of young red blood cells **just released from bone marrow** is increased to about 8.2μ. A similar increase in red cell diameter is seen in **macrocytic anemias** which may peak at 9μ. In **severe iron-deficiency anemia** and in **congenital hemolytic jaundice** the peak of the curve is at about 6μ.

As a substitute for the camera lucida drawings there have been devised micrometer disks which can be inserted into the ocular system of a microscope, and direct measurement of erythrocytes can be made with the scale on the micrometer disk. These measurements may be made on a dry stained blood film or on a wet preparation in the counting chamber, there being some shrinkage in the diameter of the red blood cells as seen in the fixed preparation when compared with the wet. In dry preparations, the average red cell diameter is 7.5μ, with a range of 7.2-7.8μ. In wet preparations, the erythrocyte diameter is 8.4μ, with a range of 7.4-9.4μ. Cells smaller than the lower values in the range are considered microcytic, and those larger than the upper figures are macrocytic.

A number of methods have been devised based on the **Pijper principle**[109] which consists essentially of the deflection of white light when passing through a screen to form a spectrum. Halometers have been produced in Europe for a good number of years, and Haden[110] produced an instrument based on this principle which is commercially available. Dingee[111] suggested a method originally described by Pryce.[112] In her ingenious technic, two 25-watt frosted electric light bulbs were placed 28 in. apart on a wall against a black background. A tape measure was fixed between the lights and was held to a stained blood film. When one looks through the blood spreads toward the 2 lights, 2 halos will be seen. The distance between the blood film and the light sources is changed until the red innermost circles of the spectrum of the 2 circles touch. The distance in feet from the lights to the blood film is then determined, and this distance corresponds to the mean diameter in μ of the red blood cells.

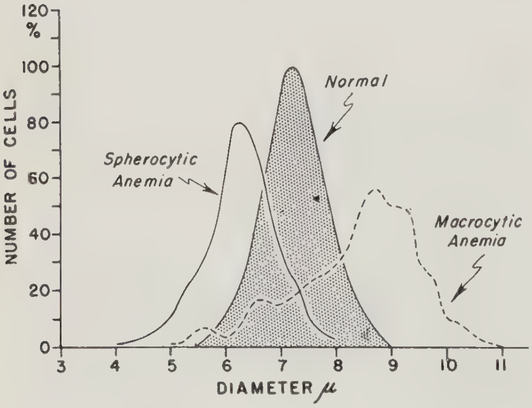

Fig. 365. Price-Jones curves.

A particularly good habit for all technicians is to make an examination of the relative size and distribution of the red blood cell population in making routine blood counts.

CONSTANTS RELATING TO HEMOGLOBIN CONTENT OF ERYTHROCYTES

Mean corpuscular hemoglobin

The mean corpuscular hemoglobin (MCH) indicates the weight of hemoglobin per average erythrocyte. The Wintrobe formula for computing mean corpuscular hemoglobin is as follows:

$$\text{MCH in micro-micrograms } (\mu\mu g) = \frac{\text{Hb in gm./1000 ml. blood}}{\text{RBC in millions/c.mm.}}$$

Normal:
Adult males: 29 μμg, average; range, 25-34
Adult females: 29 μμg, average; range, 24-33
Example:
RBC, 5,000,000; Hb, 15.6 gm./100 ml.

$$\text{MCH } (\mu\mu g) = \frac{15.6 \times 10}{5} = 31.2$$

Color index

This determination corresponds to the mean corpuscular hemoglobin. The formula is as follows:

$$\text{Color index} = \frac{\%\ \text{Hb}}{\%\ \text{erythrocytes}}$$

Normal: Normal color index averages 1.0; range, 0.85-1.15.

In the formula, 5,000,000 erythrocytes/c.mm. is usually considered 100%. As with the determination of volume index and for the sake of consistency, we recommend that the values in Table 233 be used as 100% in calculating the color index.

Examples:
Male subject:
Hb, 14.6 gm.%; 14.6 ÷ 15.8 = 92% of normal.
Erythrocytes, 4,800,000; 48 ÷ 54 = 89% of normal.

$$\text{Color index} = \frac{92}{89} = 1.02$$

Table 233. *Normal values of hemoglobin and number of erythrocytes*

	Hemoglobin	*Erythrocytes/c.mm.*
Adult males	15.8 gm.%	5,400,000
Adult females	13.9 gm.%	4,800,000

Female subject:

Hb, 4.5 gm.%; 4.5 ÷ 13.9 = 32% of normal.

Erythrocytes, 2,100,000; 21 ÷ 48 = 45% of normal.

$$\text{Color index} = \frac{32}{45} = 0.71$$

Comment on mean corpuscular hemoglobin determination

The mean corpuscular hemoglobin generally parallels changes in the mean corpuscular volume. In other words, when the red cells are smaller, the amount of hemoglobin per red cell is less. When the red cells are larger, the amount of hemoglobin is greater. But in both instances, the actual **concentration** of hemoglobin within the red cells may well be the same. In view of this, determination of the mean corpuscular hemoglobin is of relatively little value and adds very little to the knowledge already gained by determination of the mean corpuscular volume. Wintrobe stresses a determination which he feels is much more significant, the mean corpuscular hemoglobin concentration.

Mean corpuscular hemoglobin concentration

Mean corpuscular hemoglobin concentration (MCHC) expresses the concentration of hemoglobin per erythrocyte.

Normal: The normal values for mean corpuscular hemoglobin concentration, expressed in %, is 34% for both males and females, with a range of ±2%.

The formula for determining MCHC is as follows:

$$\text{MCHC } (\%) = \frac{\text{Gm. Hb/100 ml. blood}}{\text{Vol.\% of erythrocytes (Hct.)}} \times 100$$

Examples:

Normal patient:

Hemoglobin, 15.3 gm.%; hematocrit, 45 vol.%

$$\text{MCHC} = \frac{15.3}{45} \times 100 = 34\%$$

Hypochromic anemia:

Hemoglobin, 8.6 gm.%; hematocrit, 36 vol.%

$$\text{MCHC} = \frac{8.6}{36} \times 100 = 24\%$$

Comments on mean corpuscular hemoglobin concentration

Values below 30% of the mean corpuscular hemoglobin concentration are indicative of the **hypochromic** anemias. Values above 36 vol.% are not seen because there is no known condition in which the **concentration of hemoglobin per unit volume** is greater than that which occurs in the normal red blood cell. Therefore, when the term **hyperchromic** is used, it cannot be in the sense that the concentration of hemoglobin in the red blood cell has increased. Wintrobe, as well as others, decries the use of the term hyperchromic. When used in this limited sense of a greater concentration of hemoglobin per unit volume, the term is definitely a misnomer. However, when used to describe red blood cells as seen in the stained blood film, the term hyperchromic is acceptable because these cells do appear to have a greater color than normal red blood cells. This more intense coloring is due to an increased thickness of the red blood cells rather than to an increase in concentration per unit volume of the cells. When the term is understood in this manner, there is perhaps some justification for the continued use of this highly deceptive term.

The hemoglobin concentration of the red blood cell is readily apparent in properly stained blood films. Examination of such films should be made to serve as a check on the determination of mean corpuscular hemoglobin concentration. If one examines enough hematologic material, there will be a fair number of instances in which the blood spread reveals red cells that appear mildly hypochromic, whereas the mean corpuscular hemoglobin concentration is normal, and vice versa. However, when there is a marked change in the concentration of hemoglobin in red blood cells, it will be apparent in both the blood film and the mean corpuscular hemoglobin concentration determination. These two procedures should complement one another in the examination of a blood specimen.

Saturation index

Saturation index corresponds to the mean corpuscular hemoglobin concentration. The formula is as follows:

$$\text{Saturation index} = \frac{\%\ \text{Hb}}{\%\ \text{Hct.}}$$

Normal: Average, 1.0; range, 0.85-1.15.

In this calculation the problem again arises as to which values should be used for the 100%. For the sake of consistency, we recommend the values in Table 234.

Examples:

Normal male:

Hemoglobin, 15.3 gm.%; 15.3 ÷ 15.8 = 97% of normal.

Table 234. *Normal values of hemoglobin and hematocrit*

	Hemoglobin	*Hematocrit*
Adult males	15.8 gm.%	47 vol.%
Adult females	13.9 gm.%	42 vol.%

Hematocrit, 45; 45 ÷ 47 = 96% of normal.

Saturation index $= \frac{97}{96} = 1.01$.

Hypochromic anemia—female subject:

Hemoglobin, 8.6 gm.%; 8.6 ÷ 13.9 = 62% of normal.

Hematocrit, 36; 36 ÷ 42 = 86% of normal.

Saturation index $= \frac{62}{86} = 0.72$.

SUMMARY ON ERYTHROCYTE CONSTANTS

From a clinical standpoint, studies of mean corpuscular volume and mean corpuscular hemoglobin concentration in conjunction with well-prepared stained blood spreads can give inestimable information concerning the anemias. The other constants and indices are interesting but add very little to this. For speed in calculating the absolute constants, Wintrobe[113] presents a nomograph prepared by Robert E. Mason. A similar nomograph is commercially available.*

RETICULOCYTES

Reticulocytes are immature erythrocytes which show a reticulum **when stained by some supravital method. They cannot be demonstrated in a blood spread stained in the routine manner.** Reticulum may be seen in red blood cells both with or without a nucleus. The younger the reticulocyte, the more filamentous and plentiful is the reticulum. In the older reticulocyte, the reticulum may be seen as a single small bluish dot. The reticulum consists of ribonucleic acid, and with the electron microscope it can be seen to form a mitochondrial pattern. For further discussion, see also the section on hemolytic anemias.

The normal reticulocyte count is 0.5 to 1.5%. An increase in reticulocytes is evidence of active regeneration of erythrocytes.

For such a relatively simple procedure, it is amazing how many variations there are for performing this test. We shall present several methods with the admonition that features of any of these procedures may be combined to form another method.

Method of choice: new methylene blue method[114]

Reagent:

1. New methylene blue N solution.
   Dissolve 0.5 gm. new methylene blue N, 1.4 gm. potassium oxalate, and 0.8 gm. sodium chloride in 100 ml. distilled water. Filter just before use.

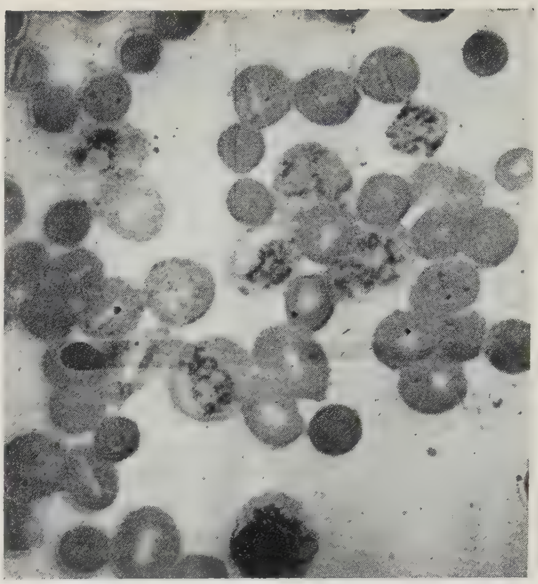

Fig. 366. Hemolytic icterus. Blood film, supravital stain, showing special staining of reticulocytes. (×950.)

Blood specimen: Venous oxalated blood can be used if used within 2-3 hr. after withdrawal from patient. Peripheral blood can also be used.

Procedure:

1. If venous blood is used, add 3 or 4 drops methylene blue N solution to an equal quantity of well-mixed blood in a small test tube and mix.
2. If peripheral blood is used, draw the methylene blue N solution into a white counting pipet until the bulb is half full, admit a small air bubble into the stem, and then draw up the blood from a fresh puncture until the bulb is filled. Mix.
3. Allow to stand 10 min.
4. Place 1 drop dye-blood mixture on the end of a clean glass slide and spread in a manner similar to that for preparing a blood film. Make several slides.
5. Dry rapidly by waving slides in the air vigorously.
6. The slide may be examined under oil immersion without further preparation, or it may be counterstained with Wright stain or Wright-Giemsa combination.

Counting reticulocytes: Using the 4-field meander method of counting, count 1000 red blood cells (250 per field), simultaneously enumerating those erythrocytes containing a reticulum (reticulocytes).

Calculation:

$$\text{Reticulocyte count in } \% = \frac{\text{No. reticulocytes counted}}{\text{No. RBC counted}} \times 100$$

Example:

46 reticulocytes counted; 1000 erythrocytes counted.

$$\% \text{ reticulocytes} = \frac{46}{1000} \times 100 = 4.6\%$$

---

*Best anemia classifier, New York, 1952, Clay Adams Co.

Method of Cook, Meyer, and Tureen

Reagents:

1. Solution A—1% solution of brilliant cresyl blue in saline.
   Dissolve 1 gm. brilliant cresyl blue by grinding in a mortar using 100 ml. warmed 0.85% sodium chloride. When cool, filter into a glass-stoppered bottle.
2. Solution B—1% solution of potassium oxalate in saline.
   Dissolve 1 gm. of potassium oxalate, neutral, in 100 ml. 0.85% sodium chloride. Filter into a glass-stoppered bottle.

Procedure:

1. Place 5 drops solution A in a watch glass.
2. Add 1 drop solution B and mix.
3. Make the puncture of the skin in the usual manner.
4. Using a Sahli pipet or capillary tube, draw up some blood and an equal amount of the mixed stain. **To avoid precipitates, do not use an excess of the stain.**
5. Mix thoroughly by alternately blowing out onto a glass slide and drawing up into the pipet. This should be done several times to ensure a good stain.
6. Allow to stand 5 or 6 min. covered with a Petri dish to prevent evaporation.
7. Place a small drop mixture of blood and stain upon the end of a glass slide and spread with a cover slip in the manner of making ordinary blood films.
8. Dry quickly to prevent distortion of the cells.
9. This slide may be examined immediately or counterstained with either Wright or Giemsa stain. If the Giemsa stain is used, the slides are fixed for 3 min. in methyl alcohol preparatory to staining.
10. Proceed as in new methylene blue method.

Comment: Although Cook, Meyer, and Tureen used the classical brilliant cresyl blue, the newer dye, new methylene blue N, could be substituted for it.

Rapid method of Schilling

This method is not permanent.

Reagent:

1. Alcoholic solution of brilliant cresyl blue, 1%.
   Dissolve 1 gm. brilliant cresyl blue in 100 ml. absolute alcohol, grinding the dye in a mortar. Filter after 24 hr. Keep in a tightly stoppered bottle with a glass rod attached.

Procedure:

1. Dip the glass rod into the solution. Spread a thin layer over a fat-free slide and allow to dry in the air.
2. Puncture the patient's skin in the usual manner and place a very small drop of blood upon the layer of dye.
3. Place a large cover glass over the drop of blood. The drop of blood must be so small that it does not spread to the edges of the cover glass.
4. Examine with oil immersion objective after about 10 min.
5. Proceed as in new methylene blue method.

Sabin method[115-118]

Materials:

1. Stock solutions.
   (a) Prepare neutral red special for supravital staining by dissolving 125 mg. neutral red in 50 ml. neutral absolute ethyl alcohol.
   (b) Prepare Janus green special for supravital staining by dissolving 125 mg. dye in 62.5 ml. neutral absolute alcohol.
2. Working solution.
   (a) Dilute 1.1 ml. stock solution neutral red in 10 ml. neutral absolute ethyl alcohol.
   (b) Add 8 drops stock solution Janus green.

Preparation of slides:

1. Flood grease-free clean slides with the working solution of Janus green-neutral red solution.
2. Drain off excess dye into working solution bottle.
3. Wipe off every drop of solution on dependent portion of slide.
4. Dry quickly by rapidly waving slide in the air or by holding it over a gentle flame.
5. Mark stained side of slide.

Slides prepared in this manner may be stored for future use, provided that this storage is free from dust. Stained films must be thin and must show even distribution of dye. Discard slides that are too thickly stained or that show uneven distribution of the stain.

Procedure:

1. Place a small drop blood on a clean cover slip and invert upon the stained surface of a neutral red-Janus green slide.
2. Seal edges of cover slip with petrolatum or a mixture of petrolatum and paraffin.
3. Allow preparation to stand 10 min. before examining for reticulocytes. The slide may be examined up to 24 hr. later if kept refrigerated at 4° C.
4. Examine under oil immersion.
5. Count reticulocytes as outlined under new methylene blue method.

Examination of Sabin-stain slides for supravital staining of leukocytes: Neutrophilic leukocytes (juvenile, stab cells, and segmented forms) move constantly with characteristic ameboid motion. The granules are numerous, small, and pale red and are constantly streaming through the cytoplasm. The nucleus usually is in the rear of the moving cell. There are present also one or more rounded bodies, presumably digestive vacuoles, which take the stain slowly. They indicate phagocytic activity, according to Sabin. They vary in color. Some leukocytes are round and motionless, the structureless nucleus nearly filling the cell and the granules, although distinctly visible, not taking the stain. These are dead or dying neutrophils. During the middle of the day, the number of these dead neutrophils is greatest. They are increased by faulty technic.

Eosinophils and basophils show red granules. The granules of the basophils are smaller than those of the eosinophils, are uneven in size, and have different staining characteristics. There are no digestive vacuoles in either cell. Eosinophils are actively motile; basophils are sluggish.

Monocytes with oval nuclei are rounded and practically nonmotile. The very fine salmon-colored granules are grouped around a clear spot, the centrosphere. There are a variable number of larger red bodies, presumably digestive vacuoles. Those monocytes with lobulated or curved nuclei are irregular in shape, usually elongated, and are sluggishly motile. The red vacuoles usually displace or obscure the fine granules.

The **lymphocytes** show a clear cytoplasm with a few small vacuoles which take the red stain. When Janus green is added, a clump of blue mitochondria may be seen opposite the nucleus. The nucleus is oval or indented. There is no motility although a few moderate-sized lymphocytes show sluggish motility.

Comment: Preparations of this kind are commonly referred to as supravital. These may be used for differential counting and blood platelet estimations, as well as for reticulocyte counting. Some workers prefer this method to the fixed spread technic. One major objection is the lack of permanence of the preparations so that preparations must be examined within 24 hr., and there are no slides available for future reference.*

The supravital method is also useful in the identification of monocytes and monoblasts and in the diagnosis of acute monocytic leukemia. It also aids in distinguishing micromyeloblasts from lymphocytes. Especially attractive is the combination of supravital staining and phase contrast microscopy as it has been described by Ackerman and Bellias. (See comments on phase microscopy.)

Comments on reticulocytes

An increase in the reticulocyte count is evidence of active regeneration of erythrocytes. The most classic reticulocytosis is that which occurs after the administration of erythrocyte maturation factor (liver extract or vitamin B_{12}) to patients with pernicious anemia in relapse. This reticulocytosis usually reaches a level of 20% by the seventh to tenth day after treatment is initiated and then drops. In part, the height of response is governed by the degree of the anemia.

Patients with iron-deficiency anemia, such as occurs with blood loss, show reticulocytosis after iron therapy. The degree of reticulocyte response is usually less than that seen in pernicious anemia under treatment. Diseases associated with hemolytic crises, such as congenital hemolytic icterus, sickle cell anemia, and erythroblastosis fetalis, may show exceedingly high (40-60%) reticulocyte counts.

Increase in reticulocytes:
Physiologic:
- At birth
- Menstruation
- Pregnancy

In disease:
- Erythropoietic response following treatment of anemias with Fe, vitamin B_{12}, folic acid, etc.
- Blood intoxication
- Erythroblastic anemias
- Granulomatoses
- Hemolytic anemias, very high
- Following hemorrhage
- von Jaksch's disease
- Kala-azar
- Lead poisoning, very high
- Leukemia
- Malaria
- Pernicious anemia and sprue following folic acid therapy (as a response to treatment) and following vitamin B_{12} therapy
- Polycythemia vera
- Relapsing fever
- Sickle cell anemia
- Splenic tumor
- Frequently in trypanosomiasis
- In typhoid fever and brucellosis occasionally
- Many parasitic infestations

Normal or increased:
- Normal individuals

Low or absent:
- Idiopathic aplastic anemia
- Acute benzol poisoning
- In anaplastic crises of hemolytic anemias

Value of reticulocyte counts:

1. To determine the response of the pernicious anemia patient to vitamin B_{12} therapy or to confirm a diagnosis of pernicious anemia by therapeutic response
2. To aid in the diagnosis of lead poisoning and hemolytic icterus.
3. To determine whether regeneration of erythrocytes is proceeding normally and whether it occurs at all, which is of value in establishing a diagnosis of aplastic anemia.
4. To aid in the prognosis of acute hemorrhage, in which an increase denotes regeneration of erythrocytes.

For further comments on reticulocytes, see discussion of reticulocytes (p. 1132) and the discussion of stained cells (p. 1133).

FRAGILITY OF ERYTHROCYTES[120]

OSMOTIC (SALINE) FRAGILITY

General considerations

The red blood cell is surrounded by a semipermeable membrane, permeable to water and electrolytes. If a red blood cell is placed in a hypotonic solution, osmotic equilibrium will be established by drawing water into the cell, which thus swells, the degree of swelling depending on the osmotic pressure gradient. In a hypertonic solution the cell will lose water and shrink. In general, the osmotic pressure for substances in solution follows Boyle's law of gases, but in the case of red blood cells several modifying factors play a role, such as the degree of crystallization of hemoglobin, the degree of oxygen saturation, the rate of penetration, the activity of transfer enzymes, the pH and temperature of the solution, and the total red blood cell count. Because of these many variables, osmotic fragility measurements should be strictly standardized and a normal control run with each test.

---

*Permanent slides may be prepared using the method of Cook, Meyer, and Tureen or the new methylene blue method.

The red blood cell surface consists of lipid and protein interrupted by pores through which most of the hemoglobin escapes when the cell membrane is stretched in hypotonic solutions. Not all the hemoglobin escapes; some of it remains within the cell attached to the stromal network.

As will be shown in the discussion of hemolytic anemias, the hemolytic phenomenon is closely related to the red cell structure. The penetrating water and the resulting electrolyte displacement produce changes in the hemoglobin molecule so that it can escape through the pores of the cell membrane.

Normal erythrocytes suspended in 0.85% sodium chloride solution remain unchanged for hours. As the saline concentration is reduced, initial hemolysis will be noted at 0.44-0.46% and complete hemolysis at 0.32-0.30%. In vitro, this process is reversible to a certain degree and can be followed by observing the normal red blood cell becoming crenated, then discoid, and finally spherical when exposed to hypotonic solutions. When the hemoglobin leaves the cell, the stroma, the ghost, remains. As spherocytosis represents one of the stages of hemolysis, naturally occurring spherocytes exhibit an increased osmotic fragility, hemolysis often beginning at 0.70% concentration of sodium chloride and becoming complete at 0.40% concentration. Their resistance to hemolysis is thus markedly lowered.

Whenever spherocytes occur, such as in congenital spherocytosis, acquired hemolytic anemia, hemolytic disease of the newborn due to A-B-O incompatibility, the osmotic fragility is increased. Microspherocytes have been described in chemical poisoning such as naphthalene and in burns. Decreased osmotic fragility, i.e., increased resistance, is seen in thalassemia, sickle cell anemia, erythremia, and jaundice. The initial hemolysis may be at 0.50% concentration of saline solution, and cells may still be intact at the bottom of the last tube containing 0.07% saline solution. The predominant cell in these conditions is thin and flat (target cell).

Presumptive test for increased osmotic fragility

1. Tube 1: 1 ml. 0.85% saline solution.
2. Tube 2: 1 ml. 0.50% saline solution.
3. To each tube add 0.1 ml. oxalated venous blood.
4. Mix and centrifuge.

Increased osmotic fragility is indicated by hemolysis in tube 2.

Wintrobe modification for osmotic fragility[120]

Materials:

1. Stock solution 0.75% saline.
   Prepare with precision 0.75 gm. NaCl/100 ml. distilled water.
2. Fresh venous 3:2 oxalated blood.
   A 0.5 ml. specimen from patient and from normal control.
3. Series of 18 test tubes in a rack numbered from 48 down to 14 in steps of 2, e.g., 48, 46, 44, etc., to 14.
4. Arrange a duplicate series of tubes for a control.
5. Serologic pipet, 5 ml., graduated in 0.1 ml.
6. Distilled water.

Preparation of different concentrations of saline:

1. Into each tube, add 0.75% saline solution in amounts equal to $\frac{1}{10}$ of the number on the tube; e.g., in tube 48, place 4.8 ml. of saline, in tube 46, 4.6 ml., etc.
2. To each tube add sufficient distilled water to bring the total to 5 ml.
3. The concentration of sodium chloride in each tube will be $\frac{1}{50}X \times 0.75\%$, where X represents the number of ml. of saline in the tube. In simpler terms, multiply the number on the tube by 0.015 to obtain the concentration of sodium chloride in the tube.

Example:

Tube 48 = 48 × 0.015 = 0.72% saline.

Mix all tubes thoroughly.

Procedure:

1. To each tube add 0.2 ml. patient's blood.
2. Prepare a similar series using normal blood as a control.
3. Shake tubes gently to ensure thorough mixing.
4. Place in a refrigerator for 2 hr.
5. Examine the supernatant fluid of the tubes for beginning hemolysis (faintest pink) and for complete hemolysis (no sediment of erythrocytes remaining in the bottom of the tube). Gentle centrifugation (1000 r.p.m. for 5 min.) aids observation of the supernatant fluid.

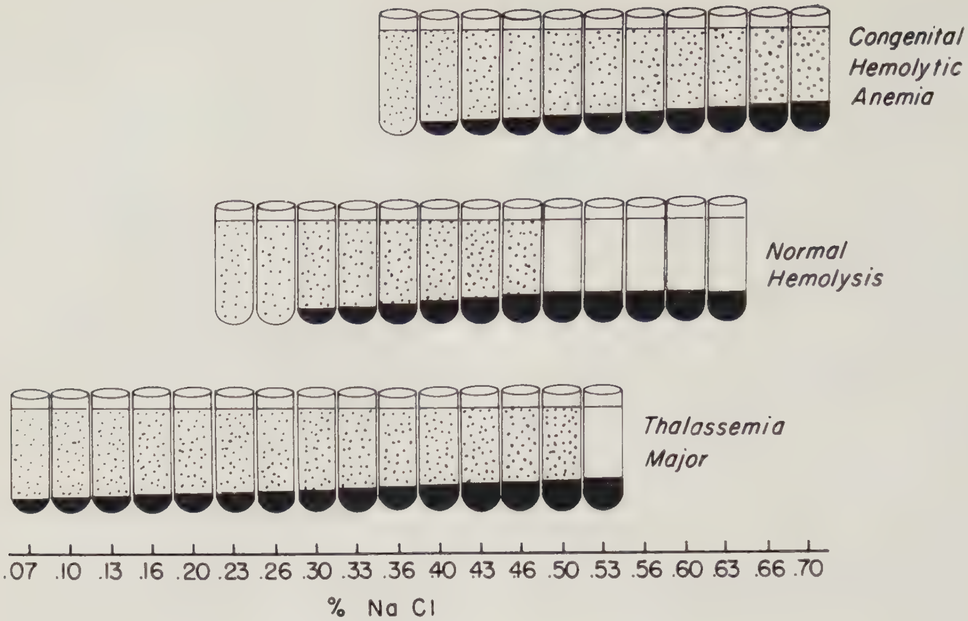

Fig. 367. Osmotic fragility (Wintrobe).

Incubation at 37° C. increases the sensitivity of this method. If incubation is used, the method is modified as follows:

Modification:

1. Defibrinate 10 ml. sterile venous blood in an Erlenmeyer flask containing 15 glass beads (3 mm. in diameter each) or use 5 ml. heparinized or oxalated (hematologic oxalate) blood.
2. Incubate at 37° C. for 24 hr. and then determine fragility as just outlined.

Normal: Hemolysis begins at 0.45-0.39% saline, is well marked at 0.42-0.36%, and is complete at 0.33-0.3%.

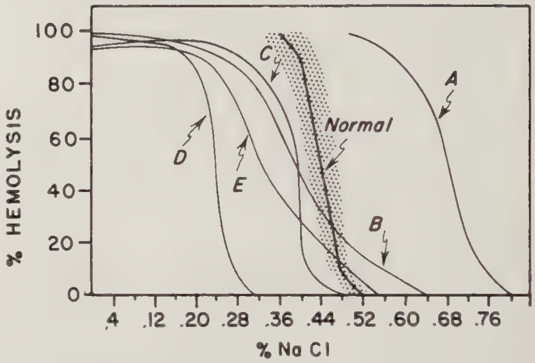

Fig. 368. Erythrocyte osmotic fragility curves (Dacie method).

Table 235. *Saline dilutions*

NaCl concentration (%)	*Vol. stock solution*	*NaCl concentration (%)*	*Vol. stock solution*
0.15	3.0	0.50	10.0
0.20	4.0	0.54	10.8
0.26	5.2	0.58	11.6
0.30	6.0	0.62	12.4
0.34	6.8	0.66	13.2
0.38	7.6	0.75	15.0
0.42	8.4	0.85	17.0
0.46	9.2		

Method of Dacie[121]

Materials:

1. Acid washed test tubes (30).
2. 5 ml. volumetric pipets.
3. Sahli hemoglobin pipets.

Principle: Blood is diluted in hypotonic saline solution and is buffered to pH 7.4 with phosphates. A series of tubes is prepared, each containing a different concentration of saline solution. After standing at room temperature the unlysed cells and ghosts are removed by centrifugation, and the degree of hemolysis in each tube is determined spectrophotometrically. A tube in which blood is diluted in water so that all of the cells lyse is used as a 100% hemolysis standard.

Reagents:

1. Stock solution.
   Dissolve 45 gm. NaCl, 6.83 gm. Na_2HPO_4, and 1.08 gm. $NaH_2PO_4 \cdot H_2O$ in distilled water and dilute to 1 L. This stock solution is osmotically equivalent to 5% NaCl and is diluted to prepare working solutions.
2. Working solutions.
   Dilute the volumes of the stock solution to a total volume of 100 ml. with distilled

water, as in Table 235. These standards are stable indefinitely if refrigerated.

Procedure:

1. Use heparinized blood.
2. Measure 5 ml. each NaCl solution into a properly labeled tube and at the same time measure 5 ml. distilled water into a tube and label 100% hemolysis.
3. Allow all tubes to warm to room temperature.
4. Add 0.02 ml. blood to each tube, mix the contents gently, and allow to stand at room temperature for 60 min.
5. Centrifuge 5-10 min. at 2000 r.p.m. and transfer the supernatant solutions to cuvets.
6. Set the wavelength dial of the spectrophotometer at 540 mμ, or if a filter photometer is used, insert a 520 or 540 mμ filter.
7. Set the instrument at zero optical density using the supernatant fluid from the 0.85% NaCl tube as reference and determine the optical density of each supernatant fluid.

If the scale of the photometer used is graduated only in % T, these values should be obtained and then converted to OD.

Determine the % lysis in each NaCl solution by dividing its OD by that of the tube in which 100% hemolysis occurred and multiplying by 100.

Example:

Reading of 0.46% NaCl = 0.240
Reading of 100% lysis tube = 0.600

If % hemolysis in each tube is plotted against its NaCl concentration, a sigmoid-shaped curve will be obtained.

Discussion: There are 3 primary influences that affect the accuracy of this determination: (1) the relative volumes of blood and saline, (2) the final pH of the blood-saline suspension, and (3) the temperature at which the tests are carried out.

The proportion of blood to saline chosen here is so small that the added blood has no appreciable effect on the osmolarity of the saline solutions; yet it is high enough to permit accurate photometric readings. However since so little blood is added, it is necessary to buffer the saline solutions used.

The effect of alterations in pH on osmotic fragility is perhaps more significant than any other single variable; a shift of 0.1 of a pH unit is equivalent to altering the tonicity of the saline solutions by 0.01%, the fragility of the erythrocytes being increased as the pH falls. A rise in temperature decreases the fragility, a rise of 5° C. being equivalent to an alteration in tonicity of about 0.01%. If very precise results are desired, the tubes may then be incubated in a water bath, preferably at 30° C.

The method of expressing the results of this test has varied from laboratory to laboratory. Plotting the data as suggested permits the ready determination of the distribution of the relative susceptibility to lysis of the entire erythrocyte population. It is suggested that the two most meaningful parameters are the concentration of saline in which 10% of the cells are hemolyzed and the concentration in which 90% are hemolyzed.

Normal:

10% hemolysis = 0.48-0.44% saline
90% hemolysis = 0.4-0.36% saline

Conclusions: Dacie's method[121, 122] is probably the best of a long line of possible procedures. An analysis of the curve shows it to be sigmoid in type. The slowly rising lower limb corresponds to the beginning hemolysis and swelling of the red blood cells. The steep middle portion represents the main escape of the hemoglobin, whereas the upper limb represents complete hemolysis.

In vivo the red blood cells are surrounded by an isotonic medium and therefore are not subjected to the pressure differences of the osmotic fragility tests. The mechanical fragility test is supposed to recreate the mechanical stresses to which the red blood cells are subjected in circulation and is therefore considered to be more physiologic.

MECHANICAL FRAGILITY [123-125]

Materials:

1. Mechanical shaking device.[126]
2. 50 ml. Erlenmeyer flasks.
3. Glass beads 4 mm. in diameter.
4. Incubator.
5. Sterile applicators.
6. Centrifuge and hematocrit tubes.
7. Distilled water.
8. Sodium chloride solution, 1.25%.
   Accurately weigh 1.25 gm. sodium chloride on an analytical balance and dissolve in distilled water in a 100 ml. volumetric flask. Dilute to 100 ml. with distilled water.

Procedure:

1. Draw 5 ml. blood with sterile precautions.
2. Transfer to a sterile 50 ml. Erlenmeyer flask containing glass beads and defibrinate by gentle rotation.
3. Divide the defibrinated blood into 2 parts. Use 1 part for immediate determination of mechanical fragility and incubate the other portion at 37° C. for 24 hr., and then determine the mechanical fragility of this specimen.
4. Adjust the hematocrit of the defibrinated blood specimen to 35 vol.% by adding or removing plasma.

Preparation of rotated sample (S):

1. Place 0.5 ml. adjusted sample in a 50 ml. Erlenmeyer flask in the shaking device. The flask should contain 8 glass beads of 4 mm. diameter.
2. Rotate in a mechanical rotor at 100 r.p.m. for 60 min.

3. Take duplicate 0.1 ml. samples of this rotated specimen and add each one to 1 ml. 1.25% sodium chloride solution in a centrifuge tube.

Preparation of sample showing complete hemolysis (H):

1. Add 0.1 ml. adjusted blood specimen to 1 ml. distilled water in a centrifuge tube.

Preparation of sample showing no hemolysis (O):

1. Add 0.1 ml. adjusted blood sample to 1 ml. 1.25% sodium chloride solution in a centrifuge tube.
2. Centrifuge samples S, H, and O at 1000 r.p.m. for 5 min.
3. Remove 0.5 ml. supernatant fluid of each centrifuged specimen and add this to 9.5 ml. distilled water.
4. Determine the hemoglobin of each diluted specimen in a photoelectric colorimeter.

Calculations:

$$\text{Percentage of mechanical fragility} = \frac{S - O}{H - O} \times 100$$

S = average of duplicated rotated specimens.

The sensitivity of the test can be increased by incubating the blood for 12 hr. at 37° C.

The mechanical fragility test may attain some importance in cardiac surgery, as apparently heparinized normal blood which is used in these procedures shows marked variations in mechanical fragility.

Table 236. *Normal range of mechanical fragility*

	Unincubated		*Incubated*	
Hemolysis	*Mean* %	*Range* %	*Mean* %	*Range* %
Newborn infants	7.1	1.1 to 11.5	13.4	3.7 to 21.6
Children	4.0	0 to 6.0	10.5	2.5 to 23.0
Adults	4.0	1.3 to 6.7	10.8	4.6 to 19.0

ROUTINE STAINING OF BLOOD FILMS

Preparation of glassware

Slides and cover slips: The cover glasses recommended are ⅞ in. wide, size B, square.

All new slides and cover glasses must be cleaned thoroughly before use to render them fat-free. Make a weak solution of a detergent (Alconox, etc.) by using about half a teaspoonful of detergent to a pint of warm water. Admit the slides and cover glasses into this solution, one at a time, so that the entire surface of each is in contact with the wetting agent. Allow them to remain in the solution for a period of 15 min. to a few hours. Do not leave them in too long because they become coated and cannot then be used.

Wash very thoroughly preferably in running water **until all traces of the detergent have been removed.** Place them in warm water and dry immediately, using a soft cloth. Linen which has been washed many times makes an excellent towel for drying slides. Use enough pressure in drying the slides to remove any traces of fat which may remain on the slides. Have clean slides and cover glasses on hand at all times in the laboratory. Satisfactory precleaned slides can be purchased.

If slides have been used for oil immersion magnification and are to be kept, dip them in xylol to remove the oil, then hold them at an angle and blow down the slide, blowing the xylol to the bottom of the slides, and dry the drop of xylol that remains. These slides can then be stored or filed for future reference.

If used slides are to be washed and reused, remove the oil with a cloth containing a few drops of xylol and clean in the detergent as just directed. It is recommended that slides should be used only once.

With this method no boiling, washing with soap, or using of ether and alcohol is necessary. Slides are clean and fat-free without further processing. Do not, however, allow the detergent to dry on the slides.

BLOOD STAINS

Giemsa stain

Considerable difficulty has been encountered by many workers in the manufacture of a serviceable Giemsa stain. The formula of R. D. Lillie has points of superiority over the original Giemsa stain and is available commercially.*

Giemsa stain—formula of R. D. Lillie[127]

Azure B eosinate:

1. Dissolve 10 gm. methylene blue, 85-88% dye content, in 600 ml. distilled water in a mortar. Add 6.8 ml. concentrated sulfuric acid, sp. gr. 1.835-1.84.
2. Bring to a boil.
3. Add 2.5 gm. potassium dichromate dissolved in 25 ml. distilled water.
4. Boil 20 min.
5. Cool to 10° C. or lower. Place in a refrigerator overnight.
6. Add 17.5 gm. sodium bicarbonate slowly with frequent shaking.
7. Add a 5% solution eosin Y of about 90% dye content and shake constantly until the margin of the fluid appears pale blue or bluish pink and an eosin halo is observed on filter paper. About 205 ml. will be required. Three fourths of this amount can be added at once.
8. Filter at once, preferably on vacuum funnel with hard paper.
9. When fluid has been drawn through and the surface begins to crack, add 100 ml. distilled water, let drain, and wash again with a second 100 ml. distilled water.
10. Open out the filter paper and let it lie on a larger piece of filter paper or a paper towel and dry overnight on a warm plate or in an incubator at 37° C. The drying may be accelerated by using two 100 ml. portions of acetone or preferably 95% alcohol as washes after the second wash with water. Drying at 55°-60° C. has been tried and produces quite a little alteration of the thiazin dye; less alteration occurs if acetone or alcohol washes are used, and the heating is limited to 2-3 hr. The resultant dye is the **crude azure B eosinate.**

Azure A eosinate:

1. Proceed as for the azure B eosinate, but take 5 gm. potassium dichromate in place of 2.5 gm. and dissolve it in 50 ml. distilled water.

Methylene blue eosinate:

1. Dissolve 10 gm. methylene blue in 600 ml. cold distilled water.
2. Precipitate as before with 5% eosin, filtering and drying as just described.

Methylene blue:

1. Use certified methylene blue chloride.

Solvent:

1. Equal parts of glycerin and methyl alcohol, certified.

Lillie stain:

1. Grind the azure B eosinate, azure A eosinate, methylene blue eosinate, and methylene blue (when necessary) separately into fine powder, using separate clean mortars.
2. Weigh 840 mg. azure B eosinate, 140 mg. azure A eosinate, 420 mg. methylene blue eosinate, and 280 mg. finely ground methylene blue.
3. Mix the 4 powders thoroughly and pour over the surface of 200 ml. solvent in a brown bottle or flask. Cork the container.
4. Allow the powder to settle into the solvent gradually.
5. Shake frequently for 2 or 3 days, keeping the bottle between 50° and 60° C. between shakings.

If the bottle is tightly stoppered, there will be little or no loss from evaporation, and if there is, the fluid level can be restored by addition of methyl alcohol provided the fluid level was marked on the outside with a wax pencil or a piece of adhesive.

The glycerin should be neutral, anhydrous, and of the purest grade obtainable. Use methyl alcohol special for blood work.

Filter the stain through Whatman No. 5 filter paper into clean, dry, dark bottles. The stain is ready for use and is stable. Use as for Giemsa stain, original formula.

Wright stain

Wright dye:

Aqueous solution of sodium bicarbonate, 0.5% . . .	100 ml.
Methylene blue	1 gm.

1. Grind in a mortar until all the methylene blue is in solution.
2. Place in Erlenmeyer flask to a depth of not more than 6 cm.
3. Heat in an Arnold steam sterilizer at 100° C. for 1 hr.
4. Cool. Filter through filter paper. Save the filtrate.
5. To every 100 ml. filtrate add 500 ml. 0.1% aqueous solution yellowish water-soluble eosin (eosin Y). Add the eosin solution slowly, stirring constantly, so as to form a precipitate. Test for a free eosin ring by placing a drop of the mixture on a piece of white filter paper and drying. The ring appears as a faint pink halo around a lavender spot. If the ring does not appear, add more 0.1% aqueous eosin until the ring forms. The center spot should be purple, not blue.
6. Filter through Whatman No. 5 filter paper, discarding the filtrate. Fold paper into 4 parts.
7. Save the precipitate on the filter paper.
8. Dry the precipitate in an incubator. This may require several days.

This is the stock stain. Place in a dark bottle labeled Wright dye. This dye is stable.

Wright stain solution:

1. All glassware must be absolutely dry.
2. Dissolve 0.1 gm. Wright dye, above, in 60 ml. methyl alcohol, acetone-free. The dye must be ground in a mortar, and the alcohol added slowly until all the dye is in solution. As much as 0.3 gm. may be used if desired.

---

*Gradwohl Laboratory Supply Co., St. Louis, Mo.

3. Place in a dark bottle.
4. Filter through filter paper after 24 hr.

The solution is not always stable.

Test and label the bottle with the timing as determined by the test.

Both stains are best purchased ready-made from a reliable supplier.

PREPARATION AND STAINING OF BLOOD FILMS FOR ROUTINE DIFFERENTIAL COUNTS

Prepare the patient (p. 1101), producing hyperemia. Make the puncture and discard the first 1 or 2 drops of blood.

Hold the slide between the thumb and middle finger of the left hand and pick up a very small drop of blood with the slide so that it is about ¼ inch from the end. To avoid endothelial cells do not allow the slide to come in contact with the skin.

Hold the cover glass between the thumb and the first finger of the right hand. Approach the drop with the cover glass at an angle of 30°. When the cover glass touches the drop of blood, allow the blood to run across the edge of the cover glass and then pull it across the slide to form a thin layer. Do not put any tension on the cover glass!

The film should not touch the edges of the slides; i.e., it should be margin-free. Scratch the patient's name in the center or the extreme end of the film as a permanent record. Let the films dry. In summer, cover the spreads to protect from flies, etc. Several spreads should be made at the same time.

The margin-free film is recommended because, when the blood film is allowed to spread to the edge of the glass slide, the large cells tend to accumulate in groups at the edges, and the small cells, such as small lymphocytes and normoblasts, go to the center. With a combination of margin-free films and the 4-field meander method of counting the cells, all spreads taken from the same individual at the same time by different individuals who know how to identify the cells should show the same differential count. The personal element, in other words, has been reduced to a minimum.

If the blood does not flow freely, remove the dried blood from the skin, gently wash the ear with a small amount of ether, and allow to dry. If the blood does not flow freely now, a new puncture must be made. Never squeeze the ear to produce a flow of blood.

Do not use too large a drop of blood, or the spread will be too thick. Do not pull the drop too rapidly, as the film will tend to become thick. If the film is made too rapidly, it will not extend to the end of the glass slide.

STAINING BLOOD FILMS

Giemsa stain*

Steps in technic using Giemsa stain

1. Fix blood film in methyl alcohol 3-5 min.
2. Allow to dry.
3. Neutralize the distilled water.
4. Dilute the Giemsa stain, 1 drop for each ml. neutral water.
5. Cover slides with diluted stain for 30 min.
6. Tip up slides and wash with neutral distilled water.
7. Allow to dry in the air.

The stock Giemsa stain keeps indefinitely. The diluted Giemsa stain must be prepared just before staining. The container in which the stain is diluted must be free of acids and alkalies.

It is well always to dilute the stain in the same container and after using to rinse the container thoroughly in tap water, then in neutral distilled water. The small amount of dye which adheres to the glass is not objectionable; in fact, the stain is better if made in a cylinder or flask which has been used for some time for Giemsa stain. The container should be cleaned from time to time to remove precipitates, after which it is neutralized.

Neutralizing water in staining of blood smears

Neutral distilled water is to be used in the routine staining process.

As Simmons[128] states: "A pH of 6.8 is usually satisfactory. Thoroughly mix the two salts, as shown in Table 237, in a mortar and use 1 gm. to 2000 ml. distilled water. It may be necessary to vary the amounts of phosphates to obtain the desired results. Red is increased by lowering and blue is decreased by raising the pH.

Table 237. *Buffered water (for use with Wright stain)*

pH	$Na_2HPO_4 + 2H_2O$ (gm.)	KH_2PO_4 (gm.)
6.2	1.816	9.504
6.5	2.723	8.316
6.8	4.539	5.940
7.0	5.447	4.752
7.2	6.355	3.564
7.4	7.262	2.376

"Microscopically, a properly stained blood smear will show red cells with a copper or tan color; lymphocytes with a pale blue cytoplasm and a dark blue nucleus; and neutrophiles with a finely granular pink cytoplasm and a dark purplish-blue nucleus. If these characteristics are not distinct, prepare additional slides."*

A simpler and better way of neutralizing water employs hematoxylin as an indicator. Water neutral to hematoxylin in our hands has proved better suited to staining blood cells than has water with a pH of 6.4. We have found that water which is neutral with the use of hematoxylin as an indicator has a pH of 6.8-7.0. This, therefore, gives a better approximate neutrality point than the buffer methods alluded to. The settlement of this neutrality point is especially necesssary in dealing with spreads for the diagnosis of malaria, particularly thick spreads and thick drops. Buffer tablets to be added to the water are commercially available.

---

*Certified Giemsa stain is made by the Gradwohl Laboratory Supply Co., St. Louis, Mo.

*From Simmons, J. S.: Laboratory methods of the United States Army, Philadelphia, 1931, P. Blakiston's Son & Co., p. 364.

Method for neutralization of water

Neutralize enough water for the day's work. The bottle used for storing the neutral water should preferably be Pyrex or should be a bottle that has been used for no other purpose than to hold distilled water. No rubber connections should be used on the still. If distilled water is purchased in large quantities, it should be poured, not siphoned, into the bottle that is to hold the neutralized water.

Pick up a few hematoxylin crystals with clean dry forceps and place in a test tube. Rinse the tube with the water before testing because the tube might not be neutral. Pour approximately 5 ml. of the water to be neutralized into the test tube containing the hematoxylin crystals, shake, and note the color. If the water is neutral, it will become a pale pink within 10 sec. If the water is acid, it becomes yellow and remains yellow for longer than 5 min. If it is alkaline, it becomes reddish purple immediately or before 1 min. If the water is acid, as it usually is, 1% potassium carbonate is used as a neutralizing agent. If it is alkaline as it comes from the still, it should not be used. Add the neutralizing agent, a drop at a time, to the stock bottle of water to be neutralized, shaking after the addition of each drop or two and again testing the reaction. When the test water turns pink without a trace of yellow or blue in 10 sec., it is neutral and may be used. If too much potassium carbonate has been added, the water becomes alkaline. Pour out some of this alkaline water and add the slightly acid nonneutralized water. Proceed as before until the water is neutral.

Water handled in this manner gives excellent staining results with Giemsa or Wright stain. Staining characteristics of blood cells are altered with changes in the reaction of the water.

If the water is acid, erythrocytes are bright red orange instead of light yellowish orange. All eosin stains become very bright reddish orange. The eosinophils stand out particularly brilliantly. In a count of eosinophils alone it is advisable to use the acid distilled water. The nuclei of all cells will stain a pale sky blue. The cytoplasm of all lymphocytes and monocytes is very pale blue. The neutrophilic cells become extremely pale, the nuclei staining either pale blue or pale lavender, and the cytoplasm a definite pink. The age of the various neutrophils cannot be determined accurately because of indefinite staining of the nuclei, thus rendering a Schilling count practically an impossibility. Blood platelets are very pale blue. Malarial parasites lose much of their color, the red chromatin staining very pale and the blue cytoplasm being scarcely visible.

With alkaline water erythrocytes stain blue or green. A purple cast is imparted to all blues in the preparation. The cytoplasm of lymphocytes becomes gray or lavender and cloudy; the cytoplasm of monocytes is decidedly pinkish lavender or even purple; the cytoplasm of the neutrophils is deep lavender or almost red. Eosinophils show deep gray or blue granules. The granules of all neutrophils become very intensely overstained and appear more numerous and larger than normal. This makes the detection of toxic granules impossible. Chromatin granules of all nuclei assume the appearance of large black clumps. The identification of any cells having nucleoli becomes extremely difficult. Erythrocytes not only change in staining characteristics but also seem to have no center and frequently have horny edges so that all the cells look crenated. Most leukocytes look frayed at the edges. Malarial parasites stain particularly well, but if the water is too alkaline, it is impossible to differentiate the chromatin from the cytoplasm. Blood platelets swell and stain reddish lavender. One cannot identify them by their structure but only by their size and arrangement.

Another danger in staining blood films is in **using too little of the staining solution** or in **overwashing.** Water will decolorize the stain. Slides must be washed very slightly and then allowed to stand on end to dry. In staining, the slides should be placed on a staining bridge over a staining pan, and as much diluted stain as they can accommodate should be used. If slides are understained or overwashed, the true color will be lost, the nuclei and cytoplasm will blend instead of being distinct, and most of the cells will look very fragile. Understained cells look very much like cells stained with acid water.

Refer to Fig. 370, in which are shown the effects on blood cells of neutral water, alkaline water, acid water, and excess washing after staining.

Our routine is to neutralize about 2 L. water every day. The water should be tested each day since it sometimes becomes acid or alkaline upon standing.

Diluting the stain

Dilute only as much Giemsa stain as desired for the work at hand. Whereas stock Giemsa stain is stable and does not precipitate, diluted Giemsa stain will change within an hour or two.

Measure the neutral distilled water in the flask or cylinder used for the diluted stain. Add 1 drop Giemsa stain for each 1 ml. neutral distilled water, shaking very slightly during the addition of each drop.

Do not add all the Giemsa stain at once. The matter of shaking after adding each drop is important. Do not shake the flask too vigorously, as a precipitate may form. Shake only enough to ensure a good mixture of the stain and the water. The drop should be measured with a dropper, the opening of which is not too small.

If a drop bottle is used as a container for Giemsa stain, it must be prepared by allowing neutral distilled water to stand in contact with the glass for at least a week, changing the water each day. The bottle must be dried.

The Giemsa stain (stock) may then be placed in the drop bottle.

Fixing the film

Absolutely pure acetone-free methyl alcohol must be used.

The methyl alcohol should be kept in a Coplin jar and transferred at the end of the day to a bottle which should be kept tightly stoppered.

Fix the slides by placing them in the jar of methyl alcohol for 3-5 min. Remove and allow to dry in the air. The drying of the fixative should always be hastened as much as possible.

Staining the film

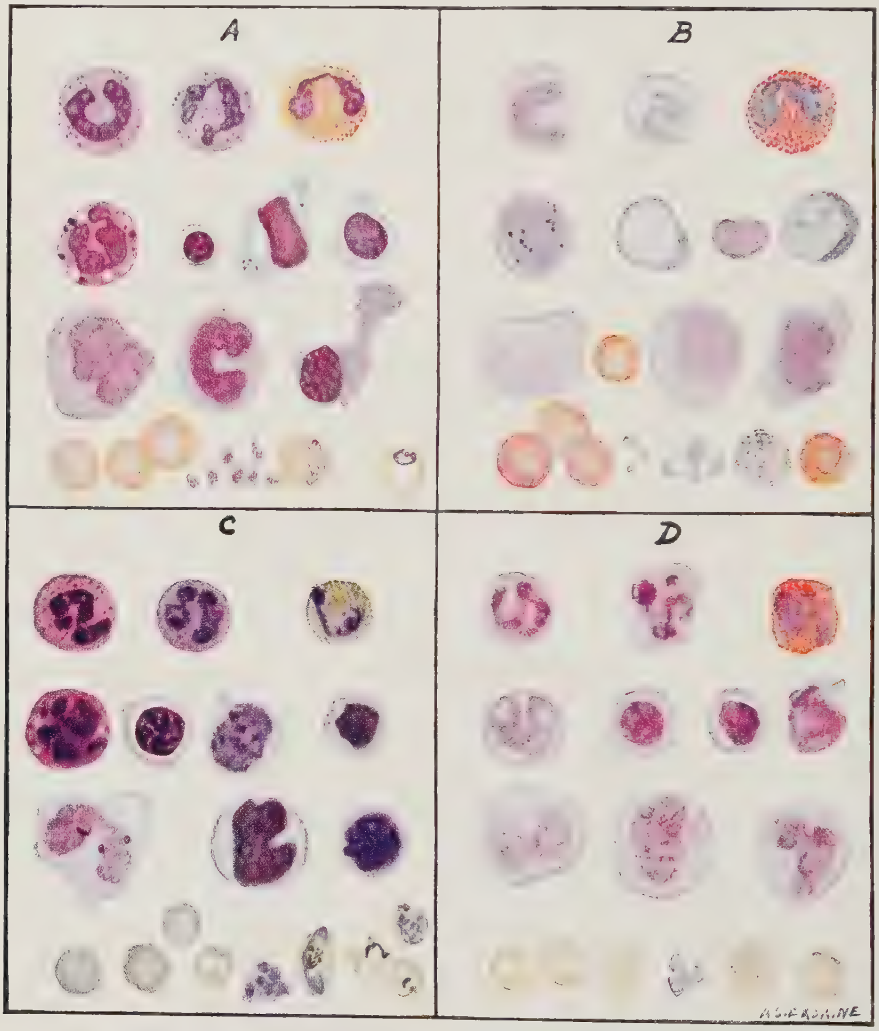
After fixation, place the slides on a staining bridge and flood them with diluted Giemsa stain. Allow the stain to remain on the slides for 30 min. or as long as 45 min. if desired. Pour off the staining mixture by gently tilting the slide and wash with neutral distilled water. The washing should not be lengthy, as too long washing will tend to decolorize the stain. Allow to dry in the air. If the slides contain an excess of blue, rewash them after they have dried and then allow them to dry in the air in a vertical position.

Rapid Giemsa method 1—McGee[129]

Stain the spread for ½ min. with a mixture of 1 part Giemsa stain to 2 parts acetone-free methyl alcohol. Mix 20 drops methyl alcohol and 10 drops Giemsa stain in a dry test tube and then flood the slide with the entire amount of this mixture for ½ min. Add an equal vol. neutral distilled water and allow the mixture to remain on the slide for 2 min. Flood the slide with neutral distilled water. Dry and examine. Use only for emergency work.

Rapid Giemsa method 2

Take equal parts of stock Giemsa stain and methyl alcohol. Stain 1 min. Differentiate until a red color appears. Dry between filter paper.



Copyright, 1935, by R. B. H. Gradwohl

Fig. 370. Blood cells and malarial parasites (Giemsa stain) with **A,** neutral water; **B,** acid water; **C,** alkaline water; and **D,** excess washing after staining. Top row: 2 neutrophils and 1 eosinophil. Second row: 1 basophil and 3 lymphocytes. Third row: monocytes. Fourth row: erythrocytes, blood platelets, and malarial parasites.

Changes in Giemsa staining to bring out special structures

For malaria: To stain blood spreads and thick drop preparations to search for malarial parasites, the water used should be slightly alkaline rather than neutral.

1. Add 1 drop 1% potassium carbonate solution to every 25 ml. neutral distilled water before adding the Giemsa stain. One drop Giemsa stain is added to each ml. water as usual (pH 7.0-7.2).

For eosinophils: To stain blood spreads and thick drop preparations to search for eosinophils, the distilled water used in diluting the Giemsa stain is allowed to remain slightly acid. The granules of the eosinophils with such staining solution stain decidedly eosin-pink.

For spirochetes: The stain should be alkalinized by adding 1 drop 1% potassium carbonate to each 10 ml. distilled water before adding the Giemsa stain.

1. Fix the slide, after drying, in methyl alcohol for 5 min. or in ethyl alcohol 20 min. Allow to dry.
2. Flood with diluted Giemsa stain, alkalinized, and steam for about 10 min. or stain cold for 24 hr.
3. Wash in running tap water for 3 min.

Spirochetes stain red. Other organisms are blue.

Wright stain

No fixative is necessary because Wright stain* contains methyl alcohol. Neutral distilled water is used. The timing of the stain must be determined when it is manufactured, but usually it is 1 min. staining and 4 min. after the water has been added.

1. Flood the slide with Wright stain and allow it to remain in contact with the film for 1 min.
2. Add neutral distilled water a drop at a time, not too slowly, until there is a mixture of equal parts of distilled water and stain.
3. Allow the mixture to remain for 4 min.
4. Flood with neutral distilled water to wash.
5. Dry in the air.

Modified technic for staining with Wright stain—Bercovitz

A slight modification of the preceding technic in making Wright stain has been suggested by Bercovitz.[130] The apparatus requires 2 staining jars with covers.

Procedure:

1. Fill one staining jar with pure methyl alcohol and the other with 30% Wright stain in distilled water.
2. Immerse the dry blood film in methyl alcohol at least 5 min.
3. Place the slide in the stain for 2 min. or longer.
4. Wash and dry as usual.

With this method there is no precipitate on the slide. The stain can be used repeatedly instead of only once. If the fluid levels of the reagents become low, add more solution to bring to the original volume. Do not discard the stain. No changes are noted even when slides are left for as long as 1 hr. in the methyl alcohol. The diluted stain can be used for several months.

May-Grünwald stain

The original communication on blood staining by the May-Grünwald method was published in *Centralblatt für innere Medizin.*[131] Granulations in the cells of sputum were demonstrated first by triacid staining as very fine red spots in the leukocytes.[132]

It was stated that these granulations were identical with the neutrophilic granulations described by Ehrlich.[133, 134]

May and Grünwald showed some interesting experiments with 4 kinds of eosin and 4 kinds of methylene blue directed toward the staining of cells and their granulations. They worked out a mixture of eosin and methylene blue directed toward the specific granulations in blood cells.

Stain and staining solution:

1. Mix 1 L. 1% eosin with 1 L. 1% methylene blue and after several days' standing filter by means of a suction pump. Wash the precipitate with cold distilled water until the filtrate is unstained.
2. Allow the sediment on the filter to dry. It consists, as seen under the oil immersion objective, of brown-red needle-form and rod-shaped crystals.

This material is slightly soluble in cold water, more so in warm water, better in ether, alcohol, acetone, etc., but best in methyl alcohol.

Make a saturated solution in methyl alcohol.

Procedure: The method of staining is the same as the Wright staining technic.

May-Grünwald-Giemsa or Wright-Giemsa staining of bone marrow and blood films

Spreads of bone marrow and blood may be stained by a combination of May-Grünwald-Giemsa or Wright-Giemsa stain. The advantages of such combined staining are that the nuclear pattern of cells is more distinctive and there is greater regularity of tinctorial reproduction from slide to slide. This combination staining shows the leptochromatic nuclear pattern of young leukocytes exceedingly well. Erythrocytes show a constancy of stain that permits evaluation of hemoglobin content.

Procedure:

1. Flood slide with Wright stain for 1½-2 min.
2. Add neutral distilled water or neutral buffer for 2 min.
3. Pour off and add dilute Giemsa stain for 7

---

*The method for making Wright stain and staining solutions is given on p. 1139.

min. for blood spreads or 10 min. for bone marrow spreads.
4. Wash off and dry.

Dilute Giemsa stain is prepared by adding 2 drops stock Giemsa stain to each ml. neutral buffer or neutral distilled water. This diluted Giemsa stain may be kept for 4-6 hr. but should not be used beyond this period.

SPECIAL METHODS OF STAINING

Oxydase staining (to determine nature of various blood cells)

Oxydase staining is a useful method of determining whether there is a definite ferment in the blood which gives specific staining to myelogenous, monocytic, and lymphatic elements. A positive reaction to the peroxidase stain is seen in the neutrophilic cells, eosinophils, well-preserved basophils, juvenile and stab cells, myelocytes, promyelocytes, and adult monocytes. The reaction is negative in lymphocytes, some monocytes, erythroblasts, and all cells which have lost their granules. The method of choice is that advocated by Graham.[135]

Graham method

This method is recommended because the stained preparations are permanent.

Solutions:

1. Formalin-alcohol.

Alcohol, 95%	90	parts
Formalin, 40%	10	parts

2. Peroxidase reagent.

Alphanaphthol	1	part
Alcohol, 40%	95	parts
Hydrogen peroxide	0.2	part

This solution should be not more than 1 wk. old.

3. Pyronin solution.

Pyronin	0.1	part
Alcohol, 40%	95	parts
Anilin oil	4	parts

Shake vigorously but do not filter.

4. 0.5% aqueous methylene blue.

Methylene blue	0.5	part
Distilled water	100	parts

Filter. This stain gives better results when diluted 3:4 after making the 0.5% solution if National Aniline dye is used.

Procedure:

1. Keep the solutions in Coplin jars.
2. Make blood films in the usual manner.
3. After drying in the air, fix in formalin-alcohol 5 min. Rinse thoroughly in running tap water. Drain but do not dry. Dry back of slide.
4. Place in alphanaphthol solution (peroxidase reagent) 5 min.
5. Rinse thoroughly in running water. Drain but do not dry. Dry back of slide.
6. Stain in pyronin solution 10 min. Wash. Drain but do not dry.
7. Stain in methylene blue solution 12-20 sec.
8. Rinse. Let dry. Examine under low-power magnification with the condenser in place to make sure that the staining solutions reacted properly. Look for definite blue stain of nuclei. If not blue enough, stain again in the methylene blue.

Myelocytic elements show red granules. **Lymphocytic** elements stain blue. All nuclei stain blue. **Monocytes** are not characteristically stained, but the "pink dust" stains red, and appears as very fine stippling.

Before staining the patient's blood film, it is best to stain a film of freshly prepared normal blood to determine timing of stains and staining characteristics. The staining solutions seem to give better results if they are allowed to stand for 24 hr. before using although they may be used immediately after manufacture in an emergency.

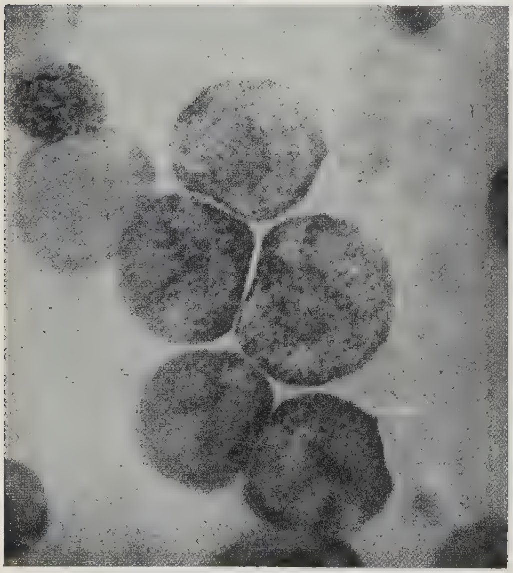


Fig. 371. Myelocytic leukemia. Blood spread, Graham oxydase stain, showing selective staining of granules. (×950.)

Oxydase reaction according to methods of Sato and Sekiya

Reagents:

1. Copper sulfate.
   Dissolve 0.5 gm. copper sulfate in 100 ml. distilled water.
2. Benzidine solution.
   Moisten 0.02 gm. benzidine, special for blood, with a few drops of water. Then grind. Add 200 ml. distilled water and filter. To filtrate add 0.25 ml. 3% hydrogen peroxide. Keep this solution in a brown bottle in the dark when not in use. It will remain good for a year although some precipitation occurs.
3. Safranin, 1% aqueous solution.

Procedure:

1. To a fresh, dry blood film apply the copper sulfate solution for 20 sec.
2. Drain off and apply the benzidine solution for 8 min.

3. Drain this off and add the safranin solution for 2 min.
4. Wash and dry.
5. Examine under oil immersion.

The peroxidase granules of myelocytes and segmented neutrophils have a deep green-blue color, whereas the nuclei are stained orange with the counterstain. Granules vary in number and size. Eosinophils show large heavy granules. Myelocytes show only a few granules; the younger they are, i.e., the nearer in age to the myeloblast, the fewer granules they have. The lymphocytes have no granules and the monocytes only a few near the nucleus. This reaction magnifies granules and serves to distinguish between the white cells of bone marrow origin and those of lymphocytic or reticuloendothelial origin.

To count oxydase stained spreads of blood

Use the 4-field meander method of counting (p. 1157). Count 200 cells, 50 in each field. Record these simply as oxydase-positive (myelocytic) elements, oxydase-negative (lymphocytic) elements, and oxydase-partially-positive (monocytic) elements. Report the percentage of each type of cell. For example:

		Normal
Myelocytic elements (oxydase-positive) . . .	85%	(63-77%)
Lymphocytic elements (oxydase-negative) . . .	13%	(21-30%)
Monocytic elements (oxydase-partially-positive)	2%	(4 to 8%)

In the preceding report, if this is leukemia, obviously it is myelocytic. The normal white cells of the differential count, when oxydase stained, occur in the following numbers: oxydase-positive, 63-77%; oxydase-negative, 21-30%; oxydase-partially-positive, 4-8%. Myeloblasts, promyelocytes, all myelocytes, juvenile and stab cells, segmented neutrophils, eosinophils, and basophils stain oxydase-positive except in unusual cases when they do not carry the oxydase ferment. Lymphoblasts, prolymphocytes, large and small lymphocytes, and plasma cells all carry no ferment and therefore are oxydase-negative. Monoblasts, promonocytes, and mature monocytes usually have a few extremely small oxydase-positive granules.

Demonstration of siderocytes or sideroblasts[136]

Siderocytes and sideroblasts are described on p. 1169. See also the discussion of sideroblastic anemias.

Materials:

1. Spreads of blood or bone marrow.
2. Formalin.
3. 2% aqueous solution of potassium ferrocyanide.
   2 gm. potassium ferrocyanide/100 ml. distilled water. This should be aged for several days.
4. 2% Hydrochloric acid.
   2 ml. concentrated hydrochloric acid added to distilled water and diluted to 100 ml. with distilled water.
5. Stock basic fuchsin solution.
   Dissolve 1 gm. basic fuchsin in 10 ml. absolute alcohol and add 90 ml. 5% aqueous phenol.
6. Working counterstain.
   Add 6 ml. stock basic fuchsin solution to 100 ml. distilled water.

Filter all solutions just prior to use.

Procedure:

1. Place blood or bone marrow films in a Coplin jar and cover the top of the jar with a piece of absorbent paper saturated with formalin.
2. Allow the slides to remain in this formalin vapor atmosphere for 30 min.
3. Stain 1 hr. in a mixture of equal parts of ferrocyanide and hydrochloric acid solutions.
4. Wash in tap water.
5. Counterstain with dilute basic fuchsin for 30-60 sec.
6. Remove excess basic fuchsin by washing in tap water and dipping in absolute ethyl alcohol.
7. Air dry.
8. Examine under oil immersion.

Siderocytes and sideroblasts will contain iron in the form of blue-staining granules within the cytoplasm.

Heinz body stain

Method I (unstable):

1. Mix a few drops citrated blood or blood taken in EDTA anticoagulant with a double volume of filtered 0.5% methyl violet in physiologic saline.
2. Mix gently and allow to stand at room temperature for 5-10 min.
3. Examine microscopically after placing a drop under a cover glass and then blotting off excess fluid and rimming with petroleum jelly.

Method II (permanent):

1. Mix a few drops citrated blood or blood taken in EDTA anticoagulant with a double vol. physiologic saline.
2. Centrifuge for 3 min. and pour off the supernatant fluid.
3. Resuspend the cells in filtered 0.5% methyl violet in physiologic saline.
4. Centrifuge for 3 min. and pour off the supernatant fluid.
5. Make films of the sediment, air dry, and mount with balsam (synthetic).

Alkaline phosphatase stain*

Method of Kaplow[137]

Reagents:

1. Fixative solution.

Formalin (36% to 39% formaldehyde)	10 ml.
Absolute methyl alcohol . . .	90 ml.

Store in the freezing unit of a refrigerator.

2. 0.2M Propanediol stock solution.
   2-Amino-2-methyl-1, 3-propanediol* . . . . . 10.5 gm.
   Distilled water to make 500 ml.
   Store in a refrigerator.
3. 0.05M Propanediol buffer, pH 9.75.
   0.2M Stock solution of propanediol . . . . 25 ml.
   0.1N Hydrochloric acid . . . 5 ml.
   Distilled water to make 100 ml.
   Store in a refrigerator.
4. Substrate mixture, pH 9.5-9.6.
   Sodium alpha naphthyl acid phosphate† . . . . . . 35 mg.
   Fast blue RR‡ . . . . . . 35 mg.
   0.05M Propanediol buffer . . 35 ml.
   Filter and use at once.
5. Mayer aqueous hematoxylin:
   (a) Solution A.
      Hematein . . . . . . 1 gm.
      Ethyl alcohol, 90% . . . 50 ml.
   Incubate 24 hr. at 37° C.
   (b) Solution B.
      Potassium aluminum sulfate . . . . . . 50 gm.
      Distilled water to make 1 L.
   Mix solution A with solution B.
   Place the mixture in the sunlight for 3-4 wk.

Procedure:

1. Make a film of fresh blood and air dry.
2. Immerse the slide in the fixative for 30 sec. at 0° C.
3. Wash in running water for 10 sec.
4. Incubate in substrate mixture for 10 min. at room temperature.
5. Wash in running water for 10 sec.
6. Counterstain with Mayer hematoxylin for 3-4 min.
7. Wash in running water for 10 sec. and air dry.
8. Mount in synthetic balsam.

Interpretation: The granules of polymorphonuclear cells, stab and juvenile cells, and myelocytes are phosphatase positive and stain from pale brown to black, allowing grading from 0 to 4+, according to the number and color of the granules.

Grade 0 = colorless cytoplasm
Grade 1+ = pale brown cytoplasm and no granules
Grade 2+ = brown cytoplasm and occasional dark granules
Grade 3+ = dark granules
Grade 4+ = black granules

In the normal blood film, most neutrophils are Grade 0, a few are Grade 1+ to Grade 2+. In infections, trauma, infarction, severe hemorrhage, and myeloproliferative disorders, the alkaline phosphatase content of the granules is increased. In acute and chronic myelogenous leukemia, the alkaline phosphatase within the neutrophils is decreased. The alkaline phosphatase shows a significant rise (20 days) early in pregnancy and can therefore be used as a differential diagnostic test of ectopic pregnancy.[138]

Method using naphthol phosphate

The reagents for this test, which is satisfactory and rapid, can be obtained commercially.* Alkaline phosphatase deposits appear as purple spots.

SEDIMENTATION RATE OF ERYTHROCYTES†

John Hunter in 1797 is given the credit of first noting that the speed of sedimentation of the erythrocytes was increased in individuals suffering from inflammatory lesions and that this speed varied with the severity of the infection. Others (Nasse, 1836; Davy, 1839; Muller, 1844) noted the behavior of red cells but did not explain it. Interest was renewed by Fahraeus[139] in 1917. In 1920 Linzenmeier[140] worked out a technic. In this country, Friedlander,[141] Polak and Mazzola,[142] Baer and Reis[143] reported the value of the test in obstetrics and gynecology. Gruenfeld,[144] Cutler,[145] Bach and Hill,[146] Bannick,[147] and others have called attention to its usefulness in medical cases, particularly rheumatic fever and tuberculosis. Grodinsky, Lesser and Goldberger, and Smith have written of its advantages in general surgery.

Sedimentation of the erythrocytes is a complex biologic process, the basic mechanisms of which cannot be reduced to a common denominator. Fahraeus referred to the phenomenon as suspension instability, which is still a good description. The physicochemical forces which have been implicated are numerous and varied. The electrical charge of erythrocytes as related to proteins has been thought to play a role. Hoeber, Mond, and Ley note that hydrogen ion concentration influences the rate, with acidosis slowing and alkalosis accelerating it. The plasma proteins exert an influence on the sedimentation rate. Fibrinogen is perhaps the most readily demonstrable protein affecting sedimentation. In diseases associated with hypofibrinogenemia, such as liver disease, the rate is very slow and some observers have suggested that the sedimentation test be included in liver profile studies. The addition of fibrinogen to normal blood in vitro markedly accelerates settling of the erythrocytes. Meyers et al.[148] confirm this fact by in vitro experiments and call attention to α_2 globulin and gamma globulin as other protein fractions having a similar effect. These workers emphasize that the erythrocyte sedimentation rate alone "does not give any clue as to the level of any one of the responsible factors."* They offer 2 complex formulas based on plasma:cell ratio and plasma protein concentrations from which formulas they can predict the sedimentation rate. The concentration of proteins, perhaps qualitatively as well as quantitatively, in some unknown manner affects the aggregation of erythrocytes in the form of rouleaux or agglomeration.

†Part of this section is from a monograph by R. B. H. Gradwohl: The rediscovery of blood sedimentation test, Rev. de med. Trop. y Parasit. Bacteriol. 3:295, 1937.

Recently, the relationship of fibrinogen and gamma globulin to the sedimentation rate has been reinvestigated. Ruhenstroth-Bauer[149] came to the conclusion that "an increase in fibrinogen or gamma globulin is only coincidental to a high sedimentation rate and not its cause."† According to this author, the increased sedimentation rate is due to plasma proteins called **agglomerins** which resemble incomplete antibodies acting in a high molecular medium. Fibrinogen is only one fraction of the agglomerins. Antiinflammatory substances block agglomerins. Glucolipid fractions (receptors) in erythrocytes are able to combine with agglomerins, the production of which is stimulated by cellular proteins of homologous or heterologous nature. Every plasma contains an inhibitor substance which at body temperature is activated by a specific serum lipase.

The specific gravity of plasma does not play an important role because the addition of weak saline causes a diminution in sedimentation rate.

A purely physical factor in sedimentation rates can be readily demonstrated and is now common knowledge. If one sedimentation tube is set up perfectly perpendicularly and another tube of the same specimen is aligned at an angle, the latter will have a higher speed of sedimentation than the former. The temperature under which the test is performed affects the rate, the rate tending to be elevated as the temperature rises. These 2 factors are important controls in performing the test.

TECHNIC OF DETERMINING SEDIMENTATION RATE OF ERYTHROCYTES

Westergren method

Materials:

1. Westergren pipet, 200 mm. in length, 2.5 mm. diameter, graduated in mm.
2. Westergren block.
3. Tourniquet.
4. Sterile 2 ml. syringe.
5. Sterile 3.7% solution sodium citrate.
6. Alcohol, sterile sponges, and adhesive tape.
7. Watch glass.

Procedure:

1. Draw sodium citrate solution into the syringe to mark 0.4.
2. Apply the tourniquet to the patient's arm and locate the vein.
3. After disinfecting the skin, insert the needle into the vein and draw blood into the syringe up to mark 2 ml. Remove tourniquet and withdraw the needle.
4. Remove needle from syringe.
5. Draw back the plunger of the syringe and tilt back and forth several times to ensure a good mixture of the blood and citrate.
6. Eject contents of syringe into watch glass.
7. Draw the mixture into a Westergren pipet to mark 0 and place the pipet in a Westergren block in a vertical position.

The number of millimeters that the erythrocytes drop in the pipet in 1 hr. is the sedimentation rate.

Read the sedimentation of the erythrocytes in mm. at the end of 1 hr.

Normal: After 1 hr., 1-15 mm. for men; 0-20 mm. for women.

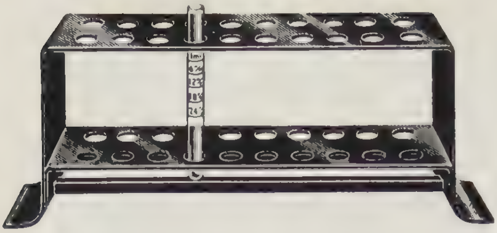

Fig. 374. Rack for use with Linzenmeier or Cutler sedimentation tubes. (Courtesy Hellige, Long Island City, N. Y.)

Linzenmeier method

Materials: Tubes 5 mm. in diameter, 65 mm. in height, with two marks, one at the level of 1 ml. and the other 18 mm. below this. Other equipment same as Westergren method.

Procedure:

1. Draw 0.2 ml. 3.7% sodium citrate solution and 0.8 ml. blood into the syringe and mix.
2. Pour the mixture into the tube up to 1 ml. mark.
3. Allow to stand in an upright position until the red blood corpuscles have settled to the mark 18 mm.
4. Note the time for this to take place. Record in minutes.

Normal: Healthy men, 350-600 min.; healthy women, 300-600 min.; menstruation, 600 minutes. Anything under 200 min. is pathologic.

Graphic or Cutler method

Materials:

1. Tubes 5 ml. capacity, graduated in 0.1 ml., each 0.1 ml. being 1 mm. in height.
2. Sterile 5 ml. syringe.
3. Freshly prepared 3% sodium citrate solution, sterile.
4. Other equipment same as Linzenmeier method.
5. Sedimentation report charts, which are available commercially.*

Procedure:

1. Draw into the syringe 0.5 ml. sodium citrate solution.
2. Draw blood to mark 5 ml.
3. Mix as in Linzenmeier method.
4. Pour contents into sedimentation tube.
5. Stopper with a paraffin-coated cork.
6. Allow tubes to stand 10 hr. but observe every 5 min. for 1 hr.
7. Draw curve on sedimentation chart.

The sedimentation value, determined by the sedimentation of the red cells in the first hour, depends

upon the sedimentation graph, the sedimentation index, and the sedimentation time. There are 4 graphs, 2 straight lines, and 2 curves. These are called horizontal line, diagonal line, diagonal curve, and vertical curve.

Sedimentation index is the total sedimentation of the red cells at the end of 60 min. expressed in mm.

Normal: Men, varies from 0-8 mm., average 3-4; healthy women, 0-10 mm., average 5-6; in menstruation as high as 12 mm.

Wintrobe-Landsberg method

Materials:

1. Wintrobe tubes and venous blood collected in 3:2 oxalate mixture (p. 1100).

   Place the filled Wintrobe tube (Fig. 375) in an exactly vertical position at room temperature and observe the point on the mm. scale to which the corpuscles fall during 1 hr.

Normal: The normal average sedimentation in 1 hr. by this method is 3.7 mm. for healthy men and 9.6 mm. for women, with a maximal range from 0.9 mm. for men and 0-20 mm. for women.

Comment: For many years it was recommended that the sedimentation rate be corrected for the volume of packed red cells. Wintrobe now believes that this adjustment is an unnecessary refinement of the procedure.[150]

Landau method[151] (modification of Linzenmeier-Raunert method)

1. Before using, clean the sedimentation pipet well with alcohol and ether and dry thoroughly in an oven or other warm place. If it is not completely dry, sodium citrate solu-

tion should be drawn up before the blood test is taken.

2. Insert capillary pipet into a precision syringe.
3. Draw up 5% sodium citrate solution by turning the top screw to the left until the upper meniscus of the solution has reached the lower mark **A.**
4. Lance finger tip or ear lobe of the patient deeply enough to get an even flow of blood without squeezing.
5. Draw up the blood until the height of the liquid reaches the upper meniscus of the upper graduation **B** and try to avoid the formation of air bubbles rising in the blood solution. If bubbles should form during the test, they can easily be expelled by means of the top screw. The suction of the blood sample can easily be performed with one hand by holding the syringe with the capillary pipet in dagger fashion with the middle, fourth, and small fingers and manipulating the top screw with thumb and index finger.
6. Clean the tip of the capillary pipet with ether and continue to draw up the mixture into the bulb (by turning top screw to the left) until the lower meniscus of the blood column ends just a few mm. below the lower opening of the bulb. (Do not draw blood into bulb completely.) The pipet may then be carefully shaken.
7. Force the blood up and down twice very slowly by turning screw to the left or right, respectively, in order to obtain a better mixture in the bulb. Force the blood gradually back into the capillary tube, close lower opening with thumb, and hold pipet firmly while turning the syringe carefully, exerting a slight pull in order to lift out the capillary pipet which is then placed into the metal stand.

The blood mixture may hang at any place in the tube but should not touch the bottom. Citrated blood should always be drawn slowly into the capillary tube; otherwise part of it will cling to the walls and air bubbles will form. If air bubbles have formed in the blood column, turn syringe upside down at an angle and force out the air bubbles by turning the screw to the right. This will push the blood column toward the opening of the pipet and thereby expel the air bubbles without the loss of much blood.

The instrument consists of a metal stand which holds either 6 or 12 capillary pipets, 12 cm. long with an inside diameter of 1 mm. Each pipet is provided with 2 graduation marks, one at 12.5 and the other at 62.5 mm. above the tip. The pipets are held in place by strong bottom springs which press the pipet against corresponding cavities provided in the screws, which are fitted into the upper part of the metal stand directly vertical above the bottom springs.

To insert the pipets into the stand, press down with the tip of the pipet against the bottom spring, and while holding it down, insert the upper part of the pipet into the cavity by gradually releasing the pressure on the spring. In the upper part of the pipet is a small bulb similar to the bulb in an ordinary blood pipet.

The precision syringe consists of a metal barrel

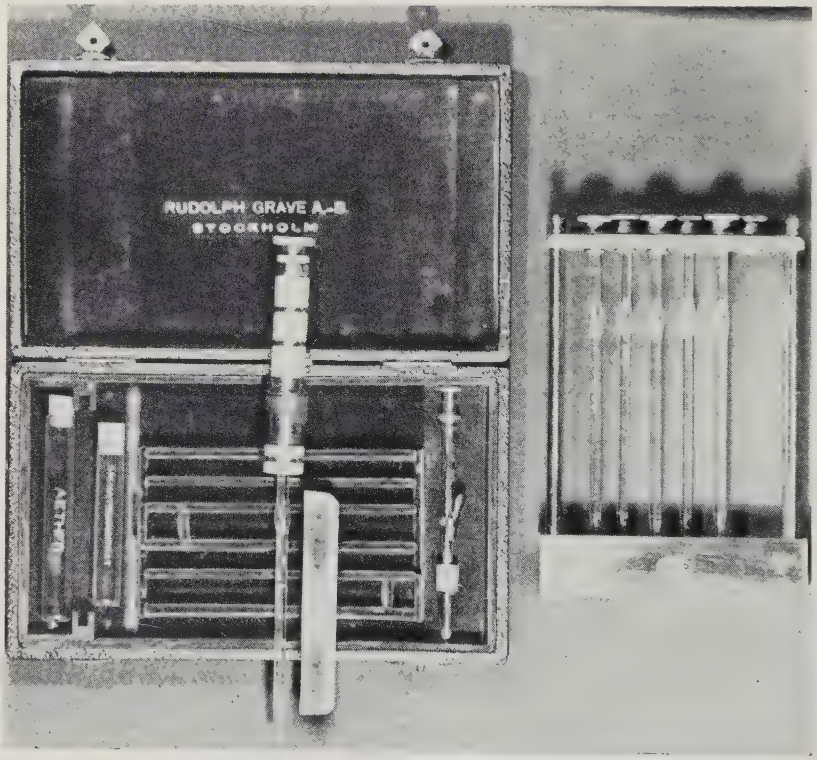

Fig. 377. Landau modification of Linzenmeier-Raunert blood sedimentation outfit.*

---

*May be procured from Clay-Adams Co., Inc., New York, N. Y.

with ground-in plunger which is adjusted by means of a screw. The lower part of the barrel has a perforated rubber stopper fitted inside into which a capillary pipet can be inserted. By adjusting the bottom screw, the size of the perforation of the stopper can be increased or decreased. Near the bottom, the barrel of the syringe has a fine opening in the side which ordinarily is covered with a piece of rubber tubing. Before inserting the capillary pipet, which already has been filled with citrated blood, into the syringe, it is necessary to roll the pointed part of the rubber tubing upward with the thumb and thus expose the side opening of the metal cylinder ordinarily covered by the tubing. By covering the tip of the capillary pipet with the finger, the pipet may be inserted into the syringe as far as it will go, and then the rubber tubing is released. In keeping the side opening of the pipet exposed, an excess of pressure in the syringe can be avoided which would tend to expel the blood. In the event that the capillary pipet has a very small outside diameter, the rubber stopper in the syringe may have to be exchanged for one with a smaller opening. If the plunger should fit too tightly, a drop of oil, dropped into the cylinder's upper part, will usually make it slide smoothly again.

The metal housing with a capacity of 6 capillary pipets is protected by a velvet-lined case which also holds glass vials for ether and 5% sodium citrate solution and automatic blood lancet, rule, rubber tubing, compartment for the precision syringe, and room for cotton and compressors. The stand, together with glass capillary pipets, can be placed in horizontal position in the case.

Results: Readings are to be made in mm. after 1 hr. The original length of the blood column is 62.5 mm.

Because of the length of the bulb, when the precision syringe is in use, only very little citrated blood will cling to the walls of the capillary pipet; thus the definite length of the column would deviate only one or a few mm. at the most from the original length, and this small difference would be of no practical importance. One can also determine the length of the column as approximately 60 mm.

Normal: For children under 2 yr. of age and for men, 1-5 mm./hr. For children over 2 yr. of age and for women, 1-8 mm./hr. Slightly increased values are 6-14 mm. and 9-14 mm., respectively. Fairly high values are 15-25 mm. High values are over 25 mm.

The Landau modification of the Linzenmeier-Raunert method of sedimentation is especially useful in pediatrics since it does not entail venipuncture. Venipuncture in children is often attended with difficulties; therefore, any method that avoids it is to be recommended.

Summary of the pertinent facts on sedimentation test

Normal:

Westergren:
  Men: 0-15 mm. after 1 hr.
  Women: 0-20 mm. after 1 hr.

Linzenmeier:
  Men: 350-600 min.
  Women: 350-600 min.
  Under 200 min. is pathologic.

Cutler:
  Men: 0-8 mm. after 1 hr. (3-4 mm. in 1 hr., average)
  Women: 0-10 mm. after 1 hr. (5-6 mm. in 1 hr., average)

Wintrobe and Landsberg:
  Men: 0-9 mm. in 1 hr. (3.7 mm., average)
  Women: 0-20 mm. in 1 hr. (9.6 mm., average)

Landau:
  Men: 1-6 mm. in 1 hr.
  Women: 1-9 mm. in 1 hr.

Comments on sedimentation rate determination

Peightal[152] very properly believes that the test is not a specific diagnostic sign for any disease but indicates the presence or absence of an inflammatory process. In some conditions it may be used in part to estimate the severity of an infection.

Landau,[151] in discussing the usefulness of microsedimentation rate in pediatrics, emphasizes its employment in arthritic and tuberculous conditions. In a number of cases, the test was useful in children, bedfast for a long time, whose primary illnesses during their stays at the hospital were followed by regularly made microsedimentation tests. In such cases an increase in sedimentation rate occurred as the symptom of a complication several days before a rise in temperature occurred. Usually the microsedimentation rate decreased much later than the temperature fell, sometimes reaching the desired value only several weeks after the temperature had become normal. Westergren considers pronounced sedimentation to be characteristic of acute polyarthritis. High values in light cases of acute polyarthritis are important as an indicator of the intensity of the process of the disease. Not until sedimentation has reached normal values after repeated tests can one regard the infectious process as having run its course.

Since apparently rheumatic illnesses are very common in Gothenburg, Sweden, Landau had numerous opportunities of testing this method in such cases. He found it quite useful in following the progress of acute polyarthritis, in acute endocarditis, pericarditis, and myocarditis, and in chorea. He has found this test very helpful in facing this important question: When, after the temperature has subsided to normal, can one venture to pronounce the endocarditic process ended in acute endocarditis? In other words, when does the endocarditis end and the vitium, the resultant condition, begin? This also raises the important question of the continued therapeutic regimen, particularly physical therapy, as well as the prognosis for cardiac function. Landau states that, in addition to cases in which the diagnosis is doubtful, microsedimentation has proved to be of extraordinary value as an indicator of disease, being generally far more sensitive than the body temperature. In routine treatment of acute polyarthritic and cardiac diseases at the Gothenburg Hospital for children, it was his custom not to release patients from bed until microsedimentation had shown normal values after repeated tests, irrespective of whether the body temperature had become normal. We do not agree that such rigidity in management is necessarily wise and that return to activity can be judged by the sedimentation test **alone.** The **total** clinical picture must be taken into account for such decisions.

In a study of 25 cases of chorea it was found that when chorea had existed as the only rheumatic condition, when polyarthritis or endocarditis had preceded it so long before that chorea could not be considered as having arisen in direct connection with these diseases, or when complicating commonplace infection could be precluded, repeated microsedimentation tests showed low values within the limits of normal. On the other hand, in cases in which the chorea arose at the same time as, or in direct connection with, polyarthritis, endocarditis, or pericarditis, microsedimentation rate was increased, and the sedimentation curve seemed to be influenced by the other diseases. It was upon this finding that Landau based his agreement with Vollenberg's hypothesis of chorea as a metarheumatic disease or as an intoxication of the cerebral cortex.

The blood sedimentation rate has been used extensively in following patients with pulmonary tuberculosis as a gauge of activity and response to therapy. In tuberculosis of the bronchial lymph nodes in children during periods of activity the blood sedimentation rate is elevated. Westergren states that blood sedimentation in bronchial lymph node tuberculosis in children after 1 hr. is 50 mm. during the period of activity. It then sinks rapidly and after 2 mo. is around 10 mm. Dehoff found that in active tuberculosis of the hilus the blood sedimentation rate with the Linzenmeier tube was such that 280 min. were required for the blood plasma to reach mark 18 mm. Rókay, using the Westergren method, found the blood sedimentation values as given in Table 238A in cases of hilar node tuberculosis.

Table 238A. *Westergren sedimentation rates in tuberculosis of hilar lymph nodes**

Sedimentation rate (mm.)	*No. of cases*	*Class I*	*Class II*	*Class III*

Blood sedimentation rate in children with polycythemia is very high, whereas in adults it tends to be low. According to Schönberger,[153] in myxedema the blood sedimentation rate is enormously accelerated, but glandular therapy may return it to normal very rapidly.

In arthritis in adults the sedimentation rate is definitely increased in the infectious or atrophic rheumatic and rheumatoid type and is normal in the noninfectious or hypertrophic degenerative osteoarthritic type.

In psychoneurotic patients with unusual symptoms in whom no organic lesion may be found, repeatedly normal sedimentation rates aid in excluding organic disease.

The sedimentation rate is retarded in asthma, hay fever, and urticaria and other allergic states.

In pertussis, with the sedimentation rate normal and a high lymphocyte count, we have an unusual condition, namely, a normal rate in a febrile disease. In all other febrile diseases, it is apparently accelerated.

It must be borne in mind that the sedimentation rate and the hemogram are both independent of the fever curve. They both may be negative or positive with and without fever, but they parallel temperature reactions only in the climax of severe inflammatory processes. Expressed in other terms, the hemogram reaction is exceedingly useful in acute infections, whereas the sedimentation rate is important in the more chronic conditions.

The sedimentation rate has been found useful in following the course of coronary occlusion in adults. The rate tends to be high early and increases as the myocardial infarction spreads. Decline in the rate occurs when the process of infarction ceases. In other cardiac diseases in adults not associated with infarction, the sedimentation rate tends to be normal.

In summary, the sedimentation rate finds a wide field of clinical applicability.[154] It is not a specific diagnostic test although it may influence differential diagnosis. Its greatest usefulness is in following the course of diseases known to have increased sedimentation rates. As an adjunct to its reflection of the progress of such diseases, the sedimentation rate acts as a yardstick of the efficacy of treatment. Although single determinations have value, **changes** in multiple determinations in a given case are of even greater significance in the evaluation of a patient.

Methodology in sedimentation rate determinations deserves some comment. The various types of apparatus and the dissimilarity of reporting results attest to the interest manifested in this procedure. In general, we feel that the test has been made unnecessarily complicated, considering its clinical usefulness. Any method with 1 reading in an hour giving the amount of settling of the erythrocytes appears quite adequate. Those methods requiring graphs of various types appear to us as unnecessary refinements.

The anticoagulant used is important. Sequestrene and heparin are not suitable unless combined with 3.8% citrate.[155] The Westergren method may lead to erroneous results because of the dilution of the blood, whereas the Wintrobe technic may also lead to wrong results in certain viscous sera (multiple myeloma) because of the absence of dilution. Dawson[156] attempted a compromise by using solid sequestrene and 1 part 3.8% citrate to 4 parts blood.

Greisheimer et al.[157] attempted to draw conclusions about the average relationship existing between the Cutler, the Linzenmeier, and the Westergren methods. They found that a sedimentation of 1 hr. for normal subjects seems to be reasonably concordant for the 3 methods despite the wide differences in tube width, anticoagulant concentration, and length of fluid column, although the differences between the means for the 3 methods are significant statistically. The average sedimentation at 1 hr. for women is approximately double that for men. They showed by tables the various indices and differences between the 3 methods and attempted to establish some ratios between them. Their tables demonstrate that the regression lines for predicting the most likely value to be expected by any one test when that by another is known are of three distinct types. There is a rectilinear relationship between the Cutler index and the Linzenmeier index. The linear regression differences between Westergren index and Cutler or Linzenmeier index appear to be somewhat like saturation curves. It was impossible to fit this into a systematic scheme by any type of mathematical equation. The relationships between the various indices and Linzenmeier time values may be suitably portrayed by sections of hyperbolae. Individual tables have been given by them for each independent variable of clinical interest. The dispersals of individual cases about the lines of average relationship, although not studied in detail, are clearly greater than those ascribable to errors inherent in the technics. It is obvious that sedimentation measures for human blood are, in part, specific for the technic employed. It would be advantageous, therefore, to have a standardized method for blood sedimentation for clinical work, but as yet this has not been done. Therefore, in estimating the importance of the sedimentation rate in any individual case, we must be familiar with the sedimentation rate in such cases, with the method used, and with the normal value for that method.

Watkins[158] emphasized the fact that variations in room temperature markedly affect the sedimentation rate. Sedimentation rate is retarded in a cooler room. Table 239 gives comparisons on stored blood and blood rechecked after 18 hours.

Table 239. *Relationship of sedimentation rate to temperature*

Case	*Room temperature reading*	*After 18 hr. at 10° C.*
1	24 mm.	(1 hr.) 3 mm. (2 hr.) 5 mm. (3 hr.) 9 mm.
2*	31 mm.	15 mm.
3†	27 mm.	25 mm.
4	24 mm.	17 mm.
5‡	(25° C.) 12 mm.	(37° C.) 20 mm.

*Hemolytic anemia.

†Pregnancy in latter months.

‡The variation between 25° and 37° C. in the sedimentation rate of erythrocytes is exactly 8 mm. There is a change from a normal or approximately normal to a definitely increased sedimentation rate of erythrocytes.

In blood sedimentation tests, either an electric light bulb or preferably a standard bacteriologic incubator can be used quite satisfactorily to supply heat. Racks containing the blood can be placed near the lamp or in the incubator. A thermometer must be placed near the blood so that records of the temperature can be made quickly and accurately. Watkins preferred the small Cutler tube for this work because (1) the smaller tube affords less surface area exposed to the reducing of temperature, (2) smaller amounts of blood can be used, (3) it is less cumbersome in handling and placing in the incubator, and (4) it maintains constant temperature. A few years ago Manley[159] devised temperature correction charts (normograms) for some of the methods.

It is important to hold the blood near body temperature until the test can be recorded. Chilling the blood before making the test will definitely alter the final results.

The **influence of anemia on the blood sedimentation rate** has been studied by many hematologists. Certain authors have suggested a correction of the sedimentation rate that takes into consideration the number of erythrocytes, the blood volume, the corpuscular volume, and the average diameter of the erythrocytes or their hemoglobin content.

According to Adura,[160] the influence of the erythrocytes on the sedimentation rate, if present at all, is very small in vivo. Therefore, for actual practice, consideration of the erythrocytes is unnecessary. The essential factors in sedimentation of erythrocytes are the physicochemical and electric alterations of the plasma. Specific weight of the erythrocytes is not to be considered a major factor. Adura points out that the sedimentation rates differ greatly in cattle and horses although the specific gravity is identical. Comparative studies made on hypochromic and hyperchromic erythrocytes showed that hemoglobin content does not materially influence the sedimentation rate. It can be shown also that the average diameter of the erythrocytes is of no significance in this respect. Adura pointed out that when erythrocytes from pregnant women or from patients with infectious diseases (accelerated sedimentation) were washed and then placed in the plasma of normal persons a normal sedimentation rate was obtained. On the other hand, when the washed erythrocytes of healthy individuals were placed in plasma of pregnant women, the sedimentation rate was greatly accelerated.

We are in agreement with Adura that these experiments prove that the plasma is the regulating factor in blood sedimentation, and that correction of the sedimentation rate on the basis of factors concerning the erythrocytes may even diminish the value of the reaction since thereby an extrinsic and inconstant factor is introduced which unnecessarily complicates the otherwise easy test.

The comments in the preceding two paragraphs have appeared in previous editions of this text. Wintrobe, who has been a strong advocate of correction of the sedimentation rate for anemia, now has abandoned such corrections as an unnecessary refinement of a crude test. Note of his present stand under the Wintrobe technic has been made, and the correction chart which formerly accompanied his technic has been eliminated. Meyers et al.[148] tried to devise some means of adjusting all sedimentation rates to a standard cell volume, and as a result of their studies cast "serious doubt on the validity of any such correction charts."[148]

Some years ago, Phear[161] reviewed this problem and found an increase in the sedimentation rate with increasing cell size but found no correlation between mean corpuscular hemoglobin concentration and the sedimentation rate.

DIFFERENTIAL COUNT

The differential count is also known as the qualitative leukocyte count. Its purpose is to determine the proportion of leukocytes of different types. This was done first in films by Einhorn[162] in 1884, followed by Kronig[163] in

1899, on spinal fluid, by Widal and Ravaut[164, 165] in 1900 (also on spinal fluid); by Simpson[166] in 1906; by Sheaff[167] in 1912; by Schilling[168] in 1913; by Nieuwenhuijse[169] and Johns[170] in 1914. Up to the announcement of Schilling in 1913, the method was known as the Ehrlich count for the reason that the types of cells described and counted were those noted by Ehrlich in his classic studies on the tinctorial qualities of various blood cells. It was Arneth who attempted to show that we might divide the immature cells into various forms and thus secure much more information as to the severity of infection present. His studies and suggestions, while essentially important, were not adopted because of the intricate details necessary to make a so-called Arneth count. Furthermore, according to Arneth's theory, leukocytes leave the bone marrow as young forms with simple indented nuclei, and these cells become changed into mature polymorphonuclear leukocytes in the circulating blood.

Schilling denies that the presence of the increased percentage of immature cell forms in the blood necessarily means an increased production of leukocytes by the bone marrow. He believes that the picture may be changed by immature cells which enter the blood being injured by bacterial or other toxins so that they fail to undergo differentiation. For instance, in typhoid fever, the decrease in the total number of white blood cells in the blood and increase in the number of immature neutrophils Schilling explains as being due, not to excessive destruction of white cells in the circulation with regenerative overactivity of the bone marrow, but rather to actual depression of marrow function, with a discharge into the blood of injured young neutrophils which do not become differentiated into the more segmented bodies. Although Schilling's work was first published in 1913, it seems to have escaped general attention, at least in the United States and practically so on the Continent, until a translation of his classic book from the German was published in 1929.[171] His remarkably simple classification of immature leukocytes, together with an interpretative formula, has been followed by a rather wholesale departure from the other methods of differential blood counting so long in vogue.

Since the popularization of the Schilling method, other methods of counting have been introduced, notably that by Cooke and Ponder in which 5 different types of cells are classified, depending upon the number of nuclear lobes. Any increase in the number of cells of the first 2 forms, i.e., the youngest type, is interpreted as a shift to the left. Then again we find the simplified Arneth count of Ponder and Krumbhaar in which neutrophils are divided into 3 classes. Finally, Farley and others have offered the filament and nonfilament neutrophil count as a method of choice in the diagnosis and prognosis of infection.

We do not find, however, that any count other than the Schilling gives as complete an understanding of the effects of infection in regard to diagnosis and prognosis.

Tabulation of differential count

The leukocytic blood picture is obtained by the differential count which consists in counting 100, 200, or 500 stained leukocytic cells, arranging them in the classification to which they belong, and reporting the percentage of each cell tabulated.

The 4-field meander method is recommended. Place a drop of oil in the middle third of each half of the film, as shown in Fig. 378. Twenty-five or 50 cells are usually counted in each field. The count is made by beginning the enumeration of the cells at the edge of the film, working toward the center (by moving the mechanical stage), going not quite to the center, and then working back to

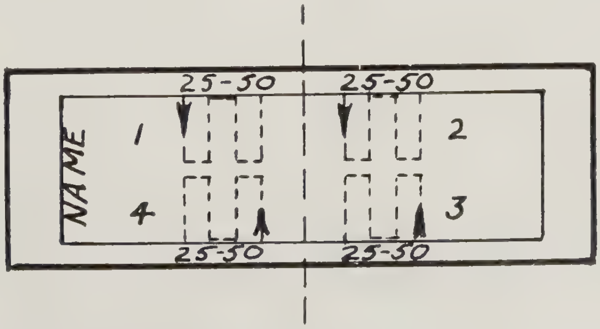

Fig. 378. "Four-field meander" method of differential counting.

BELL SIGNALS TOTAL OF EACH 100
TOTAL

Fig. 379. Marbel calculator for tabulating differential counts.

the edge and then toward the center until the desired number (25 or 50) of cells has been tabulated. After counting either 25 or 50 cells, as the case may be, shift to the next indicated field and begin the enumeration there. Continue in this manner until either 100 or 200 cells have been counted. It is our custom to count 50 cells in each field and divide the total of each cell counted by 2 to obtain the percentage of that type of cell.

Do not count only the edges since the large cells tend to accumulate there, and since the lymphocytes congregate in the center, an inaccurate count is obtained if only the center is counted. By using the 4-field meander method of counting a more accurate count is obtained.

Now construct a hemogram by recording the percentage of each cell counted. Record any abnormalities of the erythrocytes, the presence of blood parasites, and unusual staining such as toxic granules. All reports on the examination of differential counts must include an enumeration of abnormalities encountered in the erythrocytic cells. When the differential count is completed, a survey examination of the erythrocytes and platelets should be made so as not to overlook any pathologic findings.

There are various methods of mechanically computing the different cells in the differential count. The Marbel calculator is one type of instrument (Fig. 379).

Record of erythrocytic cells in differential count

In a differential count all changes in erythrocytes are noted, and a written report is made of the findings. Observe first for anisocytosis, then for poikilocytosis, polychromasia, basophilic punctation, and then for any other abnormalities of the cells. The actual numbers of all types of nucleated red cells must be given per 100 leukocytes, together with a record of karyorrhexis and mitosis. Report anisocytosis, poikilocytosis, polychromasia, and basophilic punctation as marked, moderate, or slight. Report in % the number of the various types of nucleated reds (polychromatic normoblasts, orthochromatic normoblasts, etc.) per 100 leukocytes on the slide. If Howell-Jolly bodies, Cabot ring bodies, or any other changes are noted in the erythrocytes, such findings must be recorded in the written report which is presented to the physician. In addition to the degree of basophilic punctation, it is well to report the size of the dots as fine, medium, or coarse.

The erythrocytes are classified according to the size of the majority of erythrocytes and their pigment content into 7 groups as follows:

1. Normocytic normochromic, normal-sized erythrocytes with normal pigment content
2. Normocytic hypochromic, normal-sized erythrocytes with decreased pigment content
3. Microcytic hypochromic, small erythrocytes with decreased pigment content
4. Microcytic normochromic, small erythrocytes with normal pigment content
5. Macrocytic normochromic, large erythrocytes with normal pigment content
6. Macrocytic hypochromic, large erythrocytes with decreased pigment content
7. Macrocytic hyperchromic, large erythrocytes with apparent increased pigment content (often called macrocytic normochromic)

If the majority of erythrocytes are normal in size, but there are scattered macrocytes, this would be reported as normocytic with a tendency to enlargement of the cells.

The description of the red cell series is based on the acceptance of 2 separate types of maturation of red cells as shown in the outline that follows.

There is a normal form of erythropoiesis and a megaloblastic form of erythropoiesis.

Normal erythropoiesis

Normoblast (rubriblast) → Basophilic normoblast (prorubricyte) →
Polychromatic normoblast (rubricyte) → Orthochromatic normoblast (metarubricyte) →
Reticulocyte (only special stain) → Erythrocyte (normal and abnormal forms)

Megaloblastic erythropoiesis

Promegaloblast (rubriblast, pernicious anemia type) → Basophilic megaloblast (prorubricyte, pernicious anemia type) →
Polychromatic megaloblast (rubricyte, pernicious anemia type) → Orthochromatic megaloblast (metarubricyte, pernicious anemia type) →
Megalocyte

Megaloblastic erythropoiesis, as will be shown later, is the result of vitamin B_{12} deficiency.

The description of these cells refers to cells stained with Wright or Giemsa stain. For a discussion of physiology and origin of these cells see preceding chapters.

Chapter 62

Morphology of cells in peripheral blood

JOHN D. BAUER

VARIOUS FORMS OF ERYTHROCYTES

Acanthrocytes: Acanthrocytes are thorny appearing crenated spherical erythrocytes which are usually artifacts produced in the process of making blood films or in hypotonic solutions, representing one of the stages of spherocyte formation. In contrast to the artificially produced forms, there is a genetically determined abnormality characterized by the presence of acanthroctyes (acanthrocytosis) which is associated with pigmentary degeneration of the retina.[172]

Anisocytosis: The term anisocytosis describes a variation in size of red blood cells beyond the normal limits.

Anulocytes: Anulocytes are poorly hemoglobinized cells with only a peripheral ring of hemoglobin.

Basophilic stippling: See discussion of polychromatic erythrocytes.

Burr cells[173]**:** Burr cells are erythrocytes which have long, sharp spinelike processes. They have been described in the blood in uremia and in such diseases of the stomach as carcinoma and peptic ulcer. Crenated red blood cells are characterized by short, blunt projections.

Cabot ring bodies: Cabot ring bodies are very delicate circular, figure-of-eight or loop-shaped threadlike bodies frequently seen in polychromatic or punctated erythrocytes and sometimes seen in erythrocytes with nuclear spheres. They are seen in very severe anemias. Cabot[174] described these bodies as red and blue staining circular and twisted bodies within basophilic, polychromatic, and, infrequently, orthochromatic erythrocytes. They were brought to his attention by one of his associates in a case of lead poisoning and thereafter were observed by him in the blood of patients suffering from pernicious anemia, lead poisoning, and lymphocytic leukemia. There has been much discussion in the literature as to the nature of these ring bodies. Two groups represent the division of opinion on the subject—those who advocate that the ring bodies are remnants of the nuclear membrane and those who claim that they are artifacts. Cabot's own words in his original paper are as follows: "There is no reason to believe them a mark of cellular degeneration . . . that they have some connection with the nucleus formerly possessed by the cell that contains them seems to me not unlikely . . . their shapes correspond for the most part very well with those of nuclear figures . . . the best hypothesis, therefore, that I can suggest to account for these appearances is that they represent nuclear remains . . . the significance of their red color with Wright's, a stain which never stains any nucleus red, is not clear to me . . . have these figures any practical significance? Not so far as I know."*

The following investigators believed the rings to be identical with the nuclear membrane: Schleip,[175, 176] Pappenheim,[177-179] Sluka,[180] Alder,[181] Ferrata,[182, 183] Ferrata and Viglioli,[184] Juspa,[185] and Jordan, Kindred, and Beams.[186] Demel[187] proposed that the Cabot rings are artifacts. Naegeli[188] took a middle ground by stating that Cabot rings are generally considered nuclear membrane remnants, absent in erythroblasts and the blood-forming organs; they are a pathologic phenomenon of nuclear dissolution. Schilling[189] believed that it had not been proved that the Cabot-Schleip rings are nuclear remnants. In another publication,[190] he recorded seeing Cabot rings in normal erythroblasts.

---

*From Cabot, R. C.: J. M. Res. 9:15, 1903.

Schleicher[191] has rather definitely proved that the Cabot ring bodies are denatured protein configurations and are actually laboratory products. He showed that Cabot ring bodies may be demonstrated by special methods and that they are neither nuclear remnants nor are they identical with the nuclear membrane. They are laboratory creations, the expression of cellular degeneration induced by hemolytic agents; i.e., they are the expression of aggregated and denatured colloid protein. He was able to produce these bodies experimentally. This work was carried out with egg whites on slides. He experimentally produced replicas of Cabot ring bodies in normal mature erythrocytes but not in normal erythroblasts. The creation of the bodies depends upon the physicochemical state of the lipoproteid colloids at the various maturation stages. For fuller information on the method of the experimental investigations, see his original article.

Elliptocytes: Elliptocytosis or ovalocytosis represents a congenital anomaly of red blood cells in which over 25% of the red blood cells are oval. In the camel this feature is physiologic, but in man normally only 1-15% of the red blood cells may be elliptocytes. Under pathologic conditions (macrocytic and microcytic anemias) the incidence may rise to 25%. The defect is mendelian dominant and is not sex-linked. Ovalocytosis is confined to the mature red blood cell and does not involve the precursor forms. In most cases elliptocytosis is asymptomatic, but occasionally it is associated with a hemolytic anemia (see discussion of hemolytic anemias, elliptocytosis).

Erythrocytes, crenated: Crenation occurs when red blood cells are exposed to hypotonic or hypertonic solutions. Crenated red blood cells are characterized by short, blunt, spikelike projections. Their presence, for instance, in cerebral spinal fluid indicates that the blood in the spinal fluid is not due to faulty technic (bloody tap).

Erythrocytes (normocytes): Erythrocytes or red blood cells are found normally in the circulating blood. They are biconcave disks without nuclei, 7.5-8μ in diameter and 1.7-2.2μ thick. Normal red blood cells are orthochromatic. The orthochromatic cells are the mature cells. Polychromatic cells are younger cells and may be found in the proportion of 2-10 faintly polychromatic cells/1000 orthochromatic erythrocytes in normal blood films. Red blood cells stain a uniform dull orange when orthochromatic or blue-gray when polychromatic. Any variation from this type of cell is pathologic or the result of poor technic.

Erythrocontes: Erythrocontes are fine faintly red-staining rods seen in erythrocytes, especially in the stippled cells of pernicious anemia and other conditions.

Erythrocytic crescent: Crescent bodies are delicate almost colorless veil-like disks, 40-50μ in size, with pink crescents in the margin. They might be mistaken for parasites but are nonspecific general indicators of anemia. They often result from faulty technic.

Erythrocytic shadows: Erythrocytic shadows are dehemoglobinized erythrocytes which occur in making the preparation. They are caused by lack of resistance of the erythrocytes. They stain pale pink.

Heinz bodies (inner bodies): Inner bodies are bodies in erythrocytes demonstrated with supravital staining methods. They include **Ehrlich's hemoglobinemic inner bodies. Schmauch's inner bodies** in cats are partially identical with Ehrlich's inner bodies and partially with nuclear spheres.

Heinz bodies are seen in unstained blood preparations but cannot be seen in blood films stained with Wright or Giemsa stain. These bodies stain with supravital dyes and are usually found in mature or old erythrocytes (not in reticulocytes or polychromatic cells). They occur after splenectomy and in drug-induced hemolytic anemia in which the red cells show a defect of glucose 6-phosphate dehydrogenase.[192] This enzyme maintains glutathione in a reduced state, thus protecting hemoglobin from the toxic action of drugs. Butler[193] described a Heinz body formation test using acetylphenylhydrazine which distinguishes drug-sensitive erythrocytes from nonsensitive ones. Drug-sensitive red blood cells form Heinz bodies more readily and in greater number per red blood cell. Heinz body anemia has been described in premature and full-term newborn infants. In the group of Heinz body anemias of the newborn may fall the hemolytic anemias of the newborn due to excessive doses of vitamin K to the infant as well as so-called nonspherocytic congenital hemolytic anemia and perhaps some of the cases of unexplained neonatal hyperbilirubinemia.

Fig. 381. Blood cells. (Giemsa stain.)

(See explanation of figures on opposite page.)

There is a voluminous literature dealing with the nature of the Heinz body.[194] Electron-microscopic observations suggest that changes in the stromatin[195] might be responsible for Heinz body production, whereas other work implicates methemoglobin as at least initiating the formation of these bodies.

Hemoglobin-H inclusions: These inclusions, which are sometimes found in thalassemia, are not seen in unstained cells but can be visualized with supravital stains (see discussion of abnormal hemoglobins).

Howell-Jolly bodies: Howell-Jolly bodies are peculiar spherical nuclear remnants seen in erythrocytes. They may graduate down to the size of a needle point. They are present after splenectomy and in severe anemias. They stain deep purple.

Karyogenic metachromasia (**Ferrata**)**:** Karyogenic metachromasia is a faintly wine red discoloration of erythrocytes due to the presence of fully dissolved chromatin particles. It is not found normally.

Karyorrhexis: Karyorrhexis of immature erythrocytes appears as bizarre cloverleaf nuclear shapes. This is indicative of beginning disintegration of the nucleus and is, of course, a pathologic finding. **Karyolysis** is dissolution of the nucleus of immature erythrocytes.

Leptocytes: The term is synonymous with target cells, platycytes, and Mexican hat cells (see discussion of target cells).

Macrocytes: Macrocytes are erythrocytes that are larger than normal cells, ranging up to 14μ in diameter. They contain no nuclei and are not found normally in the circulating

A.G. ERSKINE

Fig. 382. Variations in erythrocytic cells.

(See explanation of figures on opposite page.)

blood. They may be polychromatic or orthochromatic.

Marginal corpuscles: Marginal corpuscles are very small (less than $\frac{1}{4}\mu$) single or double granules in an erythrocyte in an extremely eccentric or peripheral position. They are very easily detachable, are seen in only a few erythrocytes in the film, stain red, and are seen particularly in the regenerative anemias.

Megaloblasts: Megaloblasts are never found in the circulating blood in health. The cell is slightly oval and the cytoplasm contains hemoglobin in varying quantities. The cells, therefore, may be basophilic, polychromatic, or orthochromatic; i.e., they stain a deep blue, a bluish orange, or the orange of the mature erythrocyte. The different types of megaloblasts vary in size as follows: basophilic megaloblasts, 15-22μ; polychromatic megaloblasts, 10-18μ; orthochromatic megaloblasts, 8-15μ.

By phase microscopy and electron microscopy numerous mitochondria are seen within this cell. The so-called intermediate megaloblast will be considered in the discussion of megaloblastic anemias. Suffice it to say that its nuclear chromatin pattern is coarser than that of a megaloblast of pernicious anemia. The cytoplasm lacks evidence of hemoglobinization. Its appearance is due to the addition of iron deficiency to the already existing vitamin B_{12} and folic acid deficiencies.

The nucleus is oval or round, with a fine chromatin structure. There are no granules.

Megalocytes: Megalocytes are giant erythrocytic cells (15-18 or 20μ in diameter), are usually oval, and are never found normally in the circulating blood. They have no nuclei.

Metachromatic substance (substantia metachromatica): Metachromatic substances are fine globules within erythrocytes. They are best demonstrated with supravital stain. They accumulate in one place but may be distributed, often showing lively molecular motility in the darkfield. According to Pappenheim they are lipoid segments. They probably bear some relationship to the archoplasmatic plasmasomes.

Microblasts: Microblasts are small nucleated erythrocytes which may be either orthochromatic or polychromatic. Do not confuse them with lymphocytes. The nuclear structure will make the differentiation. They are never found normally in the circulating blood.

Microcytes: Microcytes are very small red blood corpuscles (5μ in diameter), not found normally in the circulating blood. True microcytes are usually hypochromic.

Normoblasts: Normoblasts are nucleated red blood cells. They are never found normally in the circulating blood. The cytoplasm may be orthochromatic, polychromatic, or

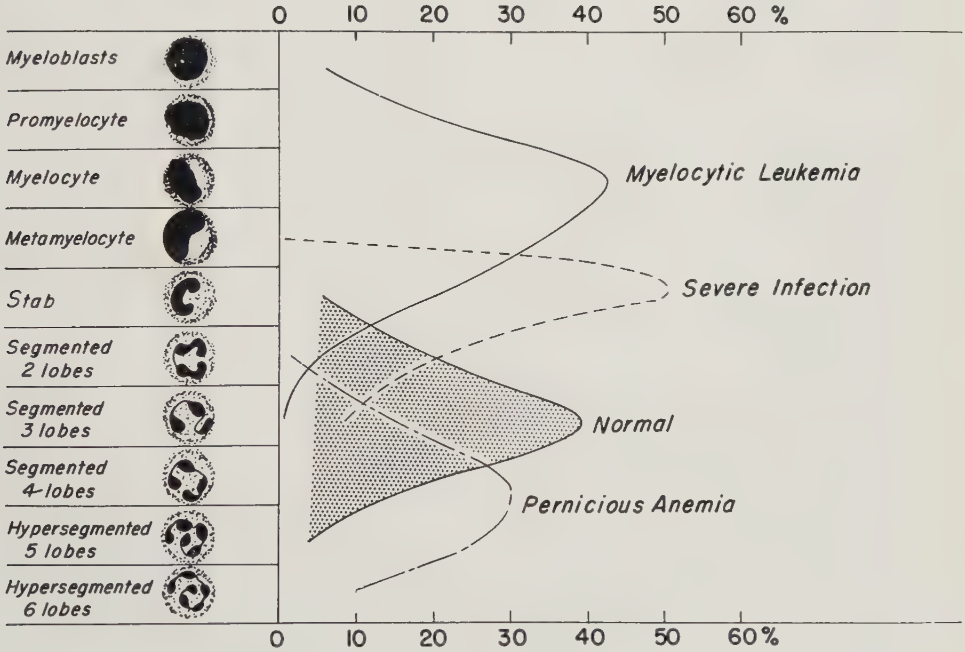

Fig. 384. Distribution of leukocytes.

basophilic. The nucleus is deep purple and contains a structure that resembles the spokes of a wheel. If the cell is overstained, the entire nucleus stains a uniform deep purple. There are no granules. Giant normoblasts are sometimes found. They are as large as megaloblasts, with small nuclei that characterize the normoblasts. Do not confuse normoblasts and lymphocytes. The polychromatic normoblast has an opaque blue or gray cytoplasm. The lymphocyte has deep blue grainy cytoplasm, with an unstained perinuclear zone usually visible. Nuclei of normoblasts are much darker than nuclei of lymphocytes, and except under conditions of degeneration they are always spherical. The round eccentric nucleus may also be confused with the nucleus of a plasma cell, but the latter has fewer chromatin spokes. The cytoplasm is basophilic and more abundant in the basophilic normoblast and orange tinged, with hemoglobin patches, in the polychromatic normoblast, and orange-red in the orthochromatic normoblast, whereas in the later phase the cell loses its nucleus, which is pyknotic and shrunken, and is expelled.

Normocytes: See discussion of erythrocytes.

Nuclear spheres: Nuclear spheres of erythrocytes are distinctly rounded droplike liquid remnants of nuclei of all sizes. They stain very dark purple. They are pathologic.

Ovalocytes: See discussion of elliptocytes.

Pernicious maculation (Mauer dots): Pernicious maculation of the erythrocytes occurs as a coarse dark violet maculation. This is seen in severe forms of falciparum malaria.

Planocytes (flat cells): See discussion of target cells.

Platycytes: See discussion of target cells.

Poikilocytes: Poikilocytes are lobulated distorted pear-shaped, oak leaf-shaped, or thorn apple-shaped degenerative forms of erythrocytes. They are found in the blood vessels following severe direct or indirect injury. They represent degenerative malformations, perhaps partially increased vulnerability. They may be artificially produced by careless technic in making the blood film.

Promegaloblasts: In size these cells are 19-27μ. The nucleus has a delicate chromatin network. There are 1-2 nucleoli present, and they are somewhat indistinct. The abundant cytoplasm is basophilic.

Polychromatic erythrocytes (basophilic stippling): Polychromatic erythrocytes are red blood cells which do not stain uniformly orange but show bluish coloration. They may or may not show stippling. Those which show stippling are called **punctated** or **stippled** erythrocytes. The term **basophilic punctation** is used to describe basophilic stippled erythrocytes. Stippling appears as fine or coarse dots stained blue or purple scattered either around the edge or throughout the entire red cell. A blood picture in which the number of polychromatic erythrocytes is increased is described as polychromasia, diffuse basophilia, or a polychromatic blood picture. One or 2 polychromatic erythrocytes may be found to every 500 normal orthochromatic cells, normally.

With the discovery of the reticulocyte in supravitally stained preparations, the question arose as to whether or not abnormal staining of this type was a sign of youth or a sign of degeneration. Hawes[196] produced evidence that the polychromatic cell of a Leishman-stained film was related to the reticulocyte of a vitally stained preparation and suggested that the stippled cell was merely a variant of the polychrome. Key,[197, 198] in 1924, confirmed the work of Hawes in relation to the polychromatic cell and pointed out that the supravital method of staining is more sensitive in detecting reticular material than is the Leishman stain for polychromasia. There is considerable doubt as to whether the stippled cell is in any way related to the reticulocyte. Piney[199] suggested that stippling may be nothing more than nuclear remnants. Samson Wright[200] in 1931, although believing that stippling is of cytoplasmic origin, did not connect it with the polychromatic cell. Maximow and Bloom[201] state: "It is possible that the stippled condition is a manifestation of immaturity much the same as polychromasia."* In this connection, Britton[202] carried out an interesting series of experiments to confirm the relation of the polychromatic cell to the reticulocyte, to establish the meaning of the phenomenon of stippling, and to determine the relation between the stippled cell and the reticulocyte and polychromatic cell. His experiments were designed to provide accurate observations on the numbers of reticulocytes, polychromatic cells, and stippled cells produced by (1) phenylhydrazine, which results in abundant polychromasia, (2) colloidal lead, which results in abundant stippling, and (3) the superposition of colloidal lead poisoning upon previously produced phenylhydrazine poisoning.

---

*From Maximow, A. A., and Bloom, W.: Textbook of histology, Philadelphia, 1930, W. B. Saunders Co.

Work was done on healthy adult rabbits which were injected intravenously with 0.44% colloidal lead and with 4% aqueous solution of phenylhydrazine hydrochloride rendered neutral to phenolphthalein with sodium hydroxide. Reticulocyte counts were made with supravital staining, and counts of polychromasia and stippling were made by determining the number of these cells in proportion to red cells which were visible in an ordinary dried Leishman-stained blood film. Large doses of the drug were used in order to produce an acute poisoning. It has been shown that repeated small doses are almost without action, and that the chronic lead poisoning of human beings is almost impossible to produce in the rabbit.

This experimental work showed that reticulocytes produced by poisoning either with phenylhydrazine or with lead are, so far as can be seen from ordinary staining, identical to normal reticulocytes. The number of polychromatic and stippled cells is paralleled by the number of reticulocytes. It seemed, according to this investigator's results, that the polychromatic material, stippling, and reticulum are the same. He obtained sufficient evidence that polychromasia and stippling are both identical to reticulation. He concluded that stippling is the same chromatic substance, slightly altered by lead or other poison, as the polychromatic characteristics of red cells in general.

Basophilic stippling occurs primarily in lead poisoning but may also be seen in hemolytic anemias and following hemorrhage. The reticulum is made visible in the cytoplasm of the cells by supravital dyes. Most of these cells are young, but a few older cells may also contain the reticulum. On electron microscopic examination it can be seen that the reticulum has a definite structure. Bessis has shown that the reticulum produces indentations, grooves, and irregularities of the cell surface. Histochemically, the cell consists of ribonucleic acid and lipids.

Reticulocytes: Reticulocytes are young polychromatic erythrocytes which show a reticulum or net structure when stained with supravital methods. These nets look like fine lines throughout the cell. Two to 10 reticulocytes to every 1000 normocytes is a normal finding.

Schistocytes (erythrocytic segments): Schistocytes are irregular erythrocytic hemoglobin-containing particles which are fragments of red blood cells. They are frequently seen in severe burns, where they are associated with microcytes less than 3μ in diameter. These cells are probably the result of the direct effect of heat on the blood. Their presence may be a useful guide to the severity of the hemolysis accompanying severe burns.[203]

Schüffner punctation (dots): Schüffner punctation is a reddish violet stippling of erythrocytes occurring in tertian malaria. They are scattered over the whole erythrocyte, occasionally appearing as distinctly connected by a reticular structure.

Siderocytes: Siderocyte is a term introduced by Gruneberg[204] to refer to red blood cells which contain nonhemoglobin iron demonstrable by the Prussian blue reaction. The iron appears in the form of blue-staining granules within the red cell and has been demonstrated in normal blood, especially after splenectomy.[205, 206] (See p. 1145 for method of staining.) In the normal peripheral blood they are present in 0-3%. They are increased in some hemolytic anemias, after splenectomy, and in lead poisoning. An increase has also been reported in newborns. (See discussion of sideroachrestic hypochromic anemia.)

Kaplan et al.[207] have studied the presence of **sideroblasts** (nucleated erythrocytes giving a positive Prussian blue reaction) in bone marrow. They found them ranging from 20-90% in normal subjects. In hypochromic anemias, there is a marked reduction in sideroblasts ranging from 0.5-1.5% but usually below 1%. With intravenous iron therapy, sideroblasts return to normal values promptly. Sideroblasts are increased in thalassemia, hemochromatosis, hemosiderosis, macrocytic anemias, hemolytic anemias, and all instances of defects of hemoglobin synthesis. Björkmann[208] and Heilmeyer[208a] described a refractory sideroblastic anemia in which there is a defect in the iron utilization and an increase in sideroblasts in the bone marrow.

Spherocytes: Spherocytes are rounded red blood cells with a diameter of approximately 4μ. In blood spreads, they appear circular and seem to have a much darker stain than the normal cells; this is due to an increased thickness. They occur most frequently in congenital hemolytic icterus but may be present in occasional cases of acquired hemolytic anemia. Electron microscopic studies show thickening of the periphery which consists mainly of so-called residual hemoglobin. Chemical studies show a diminution in the lipid contents of spherocytes and suggest the possibility of an antigen-antibody reaction interfering with normal lipid synthesis.[209] The antigen-antibody theory does not apply to the congenital hemolytic anemia in which the glucose metabolism within the cell has been found to be normal, possibly due to a defect in enzymes (enolase) that control the phosphorylation of certain phosphate esters.[210]

Spherocytes are rapidly destroyed in the spleen because stagnation in the sinusoids deprives the red cells of energy-giving glucose, and because of their enzyme deficiency they are more susceptible to glucose deprivation.[211] Apart from the previously mentioned hereditary and acquired hemolytic anemias, spherocytes are also found in A-B-O hemolytic disease of the newborn, transfusion reactions, and hemolytic anemias of burns. In A-B-O erythroblastosis the spherocytes present a valuable clue as to the diagnosis since in erythroblastosis due to Rh incompatibility they are absent. Rh erythroblastosis is usually characterized by macrocytosis.

Target cells: The term target cell was used by Barrett[212] in 1938. These peculiar erythrocytes were described in a condition called target cell anemia. This type of red cell, although described by Barrett, was really first alluded to as a special type of erythrocyte by Haden and Evans in 1937.[213] They called them dimpled corpuscles. Haden and Evans believed they were present only in sickle cell anemia, but Barett maintained that they were to be found in some cases of obstructive jaundice and severe hepatitis, in some cases of hypochromic anemia, and following splenectomy. In addition to this, Dameshek[214] described a case of target cell anemia which corresponded to what he termed an "anerythroblastic type of Cooley's erythroblastic anemia."

The description of this cell, according to Dameshek, is about as follows. The cell is abnormally thin, tends to buckle, and in stained preparations presents a bull's-eye appearance. In contradistinction to the thick spherocyte, the target cells are unusually resistant to hypotonic solutions of sodium chloride. When these cells are present in any significant number (over 4%), they result in a lengthening of the fragility span, with complete hemolysis occurring between 0.16 and 0.02%, depending upon the number of these cells present. In the cases described, hemolysis was incomplete at a concentration of sodium chloride of 0.04%. He found that a high concentration of target cells was demonstrated by examination of the centrifuged red cells from concentrations of sodium chloride below 0.3%, following resuspension in the patient's own (heparinized) plasma. When the red cells were suspended in varying concentrations of hypotonic solutions of sodium chloride and the hematocrits were determined, they were found in a concentration of 0.30, 45% hematocrit, with mean corpuscular volume of 144. The target cell is the antithesis of the spherocyte.

Bohrod[215] believes that the target cell is a newly formed cell produced by the bone marrow in response to blood loss regardless of the cause. In support of this argument, he states that the appearance of target cells in the stained blood film, far from being an unusual event, is very common. Such cells can be found in small numbers, up to 1 or 2%, early in the majority of cases of anemia. Rare ones may even sometimes be seen in apparently normal spreads. In more chronic anemias the number is variable.

Target cells are of normal diameter. In the stained spread they are made up of a rim of hemoglobin-containing area, with 2 areas being separated by a zone which is clear and unstained. Barrett believed that this appearance was due to a central knoblike projection in a cup or bowl-shaped cell and showed that a body of such shape would look like a target when viewed on the broad surface. That this is actually the shape of the cell can be seen by oblique illumination of dry films or in bas-relief photographs. No target cells are seen in wet preparations. Instead, a number of cells, equivalent to the proportion which appear as target cells in the stained film, appear as shallow or more uncommonly deep bowls or cups. When blood is diluted with hypotonic saline solutions of varying concentrations, the proportion of bowl-shaped cells or of target cells in dry films increases as the salt concentration decreases. This is due to the hemolysis of the normal appearing cells and the preservation of the target cells.

Teardrop cells: These are pear-shaped cells seen in severe anemias and are suggestive of myelofibrosis.

LEUKOCYTES (SCHILLING CLASSIFICATION)

In order to interpret differential counts of the leukocytes, it is necessary to know certain facts regarding the classification of white blood cells. White blood cells are divided into granulocytes, monocytes, and lymphocytes.

Granulocytes

Granulocytes are divided as follows:

1. **Basophilic** leukocytes (or mast cells), which are present in the circulating blood in the proportion of 0.5%. They are the cells which have an affinity for the basic dyes of the Giemsa and Wright stain.
2. **Eosinophils** (or **acidophils**) are present normally in the circulating blood and comprise 2-4% of the leukocytes. They have an affinity for acids; consequently they take the eosin stain.
3. **Neutrophils** comprise about 60-70% of all leukocytes. They require a neutral dye and consequently stain a pale pinkish lavendar or bluish lavendar.

The reddish purple granules of the basophilic cells are very irregular both in size and arrangement. The eosinophilic granules are large and are very regularly distributed throughout the entire cytoplasm of the cells so that they look very much like small pale orange balls of uniform size placed as close together as possible. The granules of the neutrophilic cells are very fine and scattered unevenly throughout the cells. They stain reddish purple.

According to Schilling's classification, there are 4 divisions of neutrophilic cells: myelocytes, juvenile cells, stab cells (rod nuclear, staff form, and other terms), and segmented forms. The myelocyte is the youngest form; the segmented form is the most mature. The myelocyte has a round to oval to kidney-shaped nucleus, with large well-filled structures and a distinct trabeculated form. Myelocytes are not found normally in the circulating blood.

Juvenile neutrophilic leukocytes have a sausage-shaped nucleus. They are identical to Pappenheim's metamyelocytes. They are found only occasionally in the circulating blood in health, in the percentage of 0-1. The stab or rod nuclear cell is found normally in health in the percentage of 3-5. They have an unbroken or rod nucleus which is capable of bending or twisting so that it is seen in many different shapes. The segmented neutrophil is found normally in the percentage of 58-66 in the circulating blood. Their nuclei have 2, 3, or more distinct segments connected by bridges. The juvenile and stab cells and segmented neutrophils were all formerly referred to as polymorphonuclear neutrophilic cells.

Classification of neutrophilic leukocytes

Arneth and Cooke as well as Schilling noted that in response to an infection young forms of neutrophils appear in the peripheral blood. Their method of recording and interpreting this phenomenon differs.

The youngest neutrophil has a C-shaped nucleus with no indentation or only a very slight one, indicating beginning lobulation in the center. As this cell matures, the nucleus develops 2-4 or even more lobes.

Arneth produced a complicated classification of neutrophils which was simplified by Cooke. Cooke divided the polymorphonuclear cells into 4 groups.

Group I: unlobed nucleus or 2-lobed nucleus, the lobes being joined by a thick bridge of chromatin; normal proportion about 10% of all polymorphonuclear cells
Group II: nucleus contains 2 lobes joined by a thin filament; proportion about 25% of all polymorphonuclear cells
Group III: 3 lobes and 2 filaments; about 47% of all polymorphonuclear cells
Group IV: 4 lobes and 3 filaments; about 16% frequency
Group V: 5 or more lobes and 4 or more filaments; 2% frequency.

In infections, toxemias, and after hemorrhage, cells of Group 1 and Group 2 increase in number, producing a shift to the left which is in proportion to the degree of toxemia and is independent of the level of the total white cell count. A shift to the right is seen in pernicious anemia and in some other types of megaloblastic anemias.

The Schilling hemogram groups all leukocytes into 3 groups—polymorphonuclears, lymphocytes, and monocytes. It divides the neutrophils into 4 groups according to age—myelocytes, juvenile cells, stab (band) cells, and segmented forms.

In the Schilling count the segmented group, which represents the oldest forms, is not further subdivided.

According to Schilling an infection produces a maturation arrest of neutrophils at the juvenile level. These cells, being unable to develop further, become stab cells and remain at this level. An infection may produce 2 reactions, a regenerative reaction and a degenerative reaction. The regenerative reaction produces myeloid stimulation of the bone marrow, with release of many young forms such as myelocytes, juvenile cells, etc., into the peripheral circulation. The degenerative reaction is an expression of the toxemia of infection and produces depression of the leukocytic marrow elements so that a decreased number of neutrophils is released into the peripheral blood stream, producing leukopenia. Most of the cells released are toxic stab cells which are unable to mature and to segment further. The proportion of normal cells to toxic granulated cells is called the **degenerative index.** In most infections both reactions interplay. According to Schilling only in an infection do the juvenile and stab cells increase over the lymphocytes and monocytes. As the infection subsides, juvenile and stab cells diminish, and lymphocytes and monocytes show a relative increase. In the healing phase, juvenile and stab cells disappear, and eosinophils increase.

Monocytes

Monocytes are more than twice the size of erythrocytes. They are normally present in the percentage of 4 to 8. It is very important to differentiate these cells from lymphocytes. (See p. 1178 for complete descriptions of all the cells.)

Lymphocytes

Lymphocytes are present in the percentage of 21-30 in normal blood. They vary in size from a cell smaller than an erythrocyte to one of the diameter of neutrophilic leukocytes. (See p. 1179 for a complete description.)

Description of leukocytes stained with Wright-Giemsa stain

Myelocytic or bone marrow cells

Myeloblasts: Myeloblasts are large bone marrow cells with a narrow to wide cytoplasm and a large nucleus. The cytoplasm is usually pale or deep blue with a thready, cloudy design. The nucleus is large, reticulated, and round with 1-6 definite nucleoli. There are no granules. Frequently the cells show vacuolization. They are oxydase-positive. They are never found in the circulating blood in health. **Micromyeloblasts** are very small myeloblasts seen only in leukemia. They resemble small lymphocytic cells but have definite nucleoli and a very deeply staining blue cytoplasm. The cytoplasm frequently shows projections thought by some authorities to be pseudopodia.

Myeloblasts may contain **Auer bodies,** which are red crystalline cytoplasmic inclusions always indicative of leukemia. The Auer bodies may also be found in monoblasts but are not seen in lymphoblasts. Auer bodies are periodic acid-Schiff positive, show a crystalline pattern under the electron microscope, and are peroxidase-positive and sudanophilic.[216, 217]

The more immature a blast cell is, the more difficult is its classification. It is therefore advisable at times to call the immature cells **stem cells.** Attempts at differentiation can be made on the basis of the company the cells keep, the presence of Auer bodies, the number of nucleoli, peroxidase staining, supravital staining, and, last, fluorescent microscopy. Stained with acridine orange, the myeloblasts have an orange tinge, whereas the lymphocytic cells are greenish.

Promyelocytes or premyelocytes: Promyelocytes are large cells. The cytoplasm is usually pale blue with fine red progranules. The granules may fill the entire cell or may be scattered around the edge of the cytoplasm. If the cell is in the center of the spread, the granules at times stain blue.* The nucleus is large and round and usually shows 1 or more nucleoli. The cell is identified by the fine red progranulation and the definite nucleoli. In leukemia, promyelocytes may be very small cells, closely resembling monocytes. They may be differentiated by the oxydase stain; these promyelocytes are oxydase-positive. They stain very much darker than monocytes and show nucleoli. The differentiation is frequently very difficult.

Neutrophilic myelocytes: The cytoplasm of neutrophilic myelocytes varies from very pale blue in the younger stages to pink in the older forms. With Wright stain, it is gray and at times intensely red. The nucleus varies in shape—round, kidney-shaped, or oval. It may or may not contain 1 or more nucleoli and is trabeculated. This nuclear structure aids in differentiating it from lymphocytes with azurophilic stippling (**small** dots). In leukemia the granules of the myelocytes are very delicate and difficult to stain. They are purple and pinpoint in size. They are seen usually only here and there; at times they may be entirely absent. In the blood stream in severe infections myelocytes usually have a pale blue cytoplasm filled with coarse neutrophilic (purple) toxic granulation. The myelocyte of leukemia has a fairly even periphery, whereas that of infections is fragile and consequently may be irregular.

Juvenile neutrophils or metamyelocytes: Juvenile neutrophils are found normally in the circulating blood in the percentage of 0-1/100 leukocytes. They are slightly larger than the mature neutrophils. The cytoplasm varies from a bluish pink to a definite pink or gray, particularly when stained with Wright stain alone. It is much wider than that of the myelocytes. The nucleus is sausage-shaped to almost bean-shaped. It does not stain intensely and shows little or no chromatin structure although it is definitely divided into fields. The granules are sometimes definite and sometimes very fine. When they are coarse, they are strikingly responsive to stain; when fine, they stain with difficulty. The same variations in staining and structure may be noted in leukemia and infections as are seen in the myelocytes. They are differentiated from stab cells by the pale nucleus without chromatin, the nucleoli, and the width of the nucleus. Stab cells are older and consequently stain more deeply, have no nucleoli, show dense chromatin structure, and have a fairly narrow nucleus. When a cell has developed beyond the juvenile stage but has not quite become a stab (borderline cell), Schilling suggests that it be called a stab.

Giant metamyelocytes are consistently found in pernicious anemia.

Stab, band, or rod nuclear neutrophilic cells: The term stab, originated by Schilling, is a German word which refers to the ability of the rubberlike rod-shaped nucleus to become bent or twisted. Stab cells are neutrophilic cells and are found in the normal circulating blood in the percentage of 3-5. The cytoplasm is pink or lavender, often gray with Wright stain. The nucleus is a flexible rod, which may be bent in making the film, so that it takes the form of the letters S, T, U, V, or W. It does not show segmentation although degeneration forms in which the nucleus is vacuolated or fringed may occur. Any cell which shows even slight segmentation is not considered a stab cell. The nucleus contains a dark chromatin structure which must not be mistaken for nucleoli. It stains more intensely than the nucleus of the juvenile cell and is slightly narrower. It does not contain nucleoli. The granules are usually distinct, very fine, purple-staining stippling and are distributed less regularly than the granules of eosinophils but more regularly than those of basophils. Under conditions of severe infections, these are very coarse and clumped. (See discussion of toxic granules, p. 1177.) When the cell is very definitely in the borderline stage between a stab and a segmented form, i.e., if it has developed farther than the stab stage, Schilling suggests that it be called a segmented cell.

It is important to remember that there are **degenerative** forms of stab cells. The degenerative forms show small band forms of nuclei—irregular, hyperchromatic, pyknotic, and structureless. They are easily broken up in making the preparation. There is a tendency toward vacuolization and diminished resistance. They are a result of a toxic element or infection. The Pelger-Huët anomaly is discussed on p. 1178.

Segmented neutrophils: Segmented neutrophils are found normally in the circulating blood in the proportion of 58-66/100 leukocytes. The diameter of the cell is about one and one-half that of an erythrocyte. The cytoplasm is usually a clear pale pink or lavender. The nucleus is usually divided into 2-5 irregular segments which are connected in a chain by fine threads or bridges. They show deep-staining chromatin structure and no nucleoli. The granules are fine, light-refracting, pale reddish violet, except in severe infections, in which they are coarse and massed in irregular clumps. These so-called **toxic granules** are also seen in the presence of malignant tumors and in splenic diseases. They may represent persistance of a myelocytic type of granulation. **Alder's anomaly**[218] consists of basophilic granulation of the neutrophils and eosinophils and is associated with gargoylism. Severely toxic segmented neutrophils may contain 2-4 pyknotic nuclear masses which are not connected and may show nuclear cytoplasmic dissociation.

Abnormalities of polymorphonuclear leukocytes

Giant hypersegmented polymorphonuclear leukocytes are usually found in pernicious anemia. The administration of colchicine, a drug that blocks mitosis, also produces giant neutrophils. The production of **giant neutrophils,** as well as of hypersegmentation of the nuclei, has been described as 2 separate types of inherited anomalies.[219]

The cytoplasm of neutrophils may show pathologic changes apart from the previously mentioned toxic granulation and Alder's anomaly. Döhle described basophilic patches in toxic polymorphonuclear cells. They are similar to the inclusions described by Hegglin,[220] but Hegglin inclusions are also found in monocytes and in lymphocytes and are associated with abnormal giant platelets. **Döhle bodies** are also somewhat similar to the irregular inclusions found in **Chediak's[221] syndrome,** which is characterized by semialbinism and enlargement of the spleen, liver, and lymph nodes.

In the **Pelger-Huët's anomaly** the nuclei of the polymorphonuclear leukocytes are not segmented but are similar to the nuclei of stab and juvenile cells. This disorder is hereditary and consists of an inability of nuclei to segment so that an apparent shift to the left is produced.[222]

This anomaly is exactly the opposite of the inherited anomaly of hypersegmentation described by Undritz.[223]

Eosinophils: Eosinophils are found normally in the circulating blood in the proportion of 2-4/100 leukocytes. The clear white or pale blue cytoplasm is composed of many highly light-refracting granules which stain a faint orange to a decided orange with the Giemsa stain. With the Wright stain, they are more intensely stained. They are usually situated so close together that they give the appearance to a casual observer of an almost uniformly orange-stained cytoplasm. The granules may be rendered more pronounced by partially closing the iris diaphragm. In young eosinophilic cells, or in mature cells if alkaline water is used in staining, there are frequently found deep blue granules. Sometimes the entire cytoplasm stains a uniform gray color, but the identification of the cell can still be made by the regularity of the granules and the shape of the nuclei. Bright crystallike granules may also be seen. This is an artificial picture due to the highly light-refracting characteristic of the granules.

Eosinophils are differentiated as eosinophilic myelocytes (if they have round or oval nuclei), eosinophilic juvenile cells (if the nuclei are like metamyelocytes), eosinophilic stab cells (with typical stab nucleus), or segmented eosinophils. It is customary not to classify the eosinophils except as myelocytes and segmented eosinophils (simply eosinophils) except when eosinophilic myelocytes are found.

The nucleus of the mature eosinophil usually has 2 segments, double pear-shaped. There are seldom more than 3 or 4 segments although it is possible to find them. Eosinophils retain their characteristics in the thick drop. To intensify the orange color of the granules, make the staining water slightly acid.

Eosinophils are responsible for the production of Charcot-Leyden crystals and of plasminogen. They are present in the stool, blood, sputum, and nasal secretions of patients suffering from allergic diseases.

Basophils or mast cells: Basophils may also be divided into basophilic myelocytes and mature cells. The mature forms are found normally in the circulating blood in the proportion of 0-1/100 leukocytes. The cytoplasm is usually very narrow and stains deep reddish purple with the Giemsa stain. With the Wright stain the cytoplasm is often blue. It is composed almost entirely of irregular basophilic fragments which usually stain intensely. These fragments are very highly soluble in water and therefore drop out of the cytoplasm during the staining process, leaving the cell appearing highly vacuolated. If the granules do not dissolve, they stain intensely reddish purple and are unevenly distributed throughout the cytoplasm. With Wright stain the granules stain a dark blue-purple. The nucleus is bizarre and lobulated and occupies most of the cell. It stains a deep reddish purple with the Giemsa stain and an intense bluish purple with the Wright stain.[224]

An increase in basophils can be seen in myelogenous leukemia but is also found in myeloproliferative disorders. The blood basophil may be only functionally related to the tissue mast cell. Both have the same function of storing and producing heparin, histamine, and serotonin. The tissue mast cell, though somewhat similar in appearance to the blood basophil, is a connective tissue cell and is frequently found in bone marrow. The tissue mast cell is larger than the blood basophil, it is oxidase negative, and the granules do not dissolve in methyl alcohol. There is a large amount of cytoplasm, and the cell is never found in the peripheral blood.

An increase of tissue mast cells has been reported in macroglobulinemia. The basophilic granulocyte should be clearly separated from the connective tissue mast cell. Mast cell proliferation, even leukemia, has been described in association with urticaria pigmentosa (mastocytosis) and also in association with adrenal cortical hyperfunction and with anaphylaxis.[225, 226]

Cells from reticuloendothelial system

Monocytes: Monocytes were formerly called large mononuclear cells and transitional cells. They are found normally in the circulating blood in the proportion of 4-8/100 leukocytes. They are usually much larger than the granulocytes but may be as small as a small lymphocyte. The cytoplasm is usually very wide, is smoky blue to pale pinkish violet or blue, and is frequently covered with a very fine pink dust. It may or may not show vacuoles. The cell shows a very irregular outline, which helps differentiate it from lymphocytes. The nucleus is fairly large and may vary from oval to bean-shaped or kidney shape or may even show lobulation. Occasionally it closely resembles the nucleus of the juvenile neutrophil. It can easily be differentiated by the color and structure of the cytoplasm. Sometimes a sausage-shaped nucleus is seen, and at times nucleoli are distinctly visible. The edges are seldom if ever smooth; the contour appears wrinkled instead of smooth or flat. Monocytes are usually granulated, the cytoplasm being filled with very fine pink dustlike granules which when stained intensely may be mistaken by the beginner for neutrophilic granules. They are, however, less distinct than neutrophilic granules and are possible of differentiation. Very large phagocytic monocytes have been called **macrophages.** Monocytes are slightly oxidase-positive.

There are ill-defined boundaries between monocytes, lymphocytes, and plasma cells. In the bone marrow of macroglobulinemia various transition forms have been described.[227] The term **virocytes** has been coined to describe cells which have characteristics of both lymphocytes and monocytes and which appear in virus diseases such as infectious mononucleosis, hepatitis, viral upper respiratory infections, roseola, etc. These cells are probably transitional forms which may correspond to the cells which make up the germinal center of lymph nodes.

Unlike the lymphocytes, the monocytes do not show a perinuclear unstained zone. Differentiation of these cells from lymphocytes is made as follows.

1. Monocytes are usually larger than lymphocytes, but the size is not a point in differentiation if all other characteristics show the cell to be distinctly monocytic.
2. The nucleus of the monocyte is wrinkled; that of the lymphocyte is smooth and solid and usually shows deeply stained chromatin material. The monocyte occasionally shows nucleoli.
3. The structure of the monocyte is reticulated and more delicate than the structure of the lymphocyte; therefore, the cell stains paler than the lymphocyte.
4. The monocytes tend to show great variations in the shapes of the nuclei.
5. The lymphocyte usually shows a clear, unstained perinuclear zone, whereas the monocyte is usually devoid of such a zone.
6. The monocyte shows a pink, powdery granulation, whereas the lymphocyte is either without granules or shows azurophilic stippling.
7. The cytoplasm of monocytes is smoky blue, gray, or lavender, whereas that of lymphocytes is a definite clear pale or deep blue.

Monoblasts: Monoblasts are immature monocytic cells and are larger than mature monocytes. They are never found normally in the circulating blood. They are irregular in shape. The nucleus is in the form of an irregular crescent or is broad and elongated. It might be bent over itself several times, giving the impression of lobulation. It has a loosely woven chromatin network and often stains paler than lymphoblasts and myeloblasts. The cytoplasm is more abundant and less basophilic than that of lymphoblasts. Azure granules may be seen; vacuolization is common. They exhibit lively ameboid movements and may be either oxidase positive or negative. The cytoplasm may contain Auer bodies. (See discussion of myeloblasts.)

Endothelial cells: Endothelial cells are long caudate cells and frequently have a conspicuous oval, eccentric, finely designed nucleus. At times nucleoli are visible. The cytoplasm is very delicate and if visible stains either very pale pink or very pale blue. There seem to be fine pink granules or dust throughout the irregular cytoplasm, although this may be absent.

Lymphocytic cells

Lymphoblasts: Lymphoblasts are never found normally in the circulating blood. The cytoplasm is usually deep blue with a threadlike cloudy design appearance. It is usually narrow and has a smooth edge. At times, however, cytoplasmic projections said to be pseudopodia are observed. The nucleus is large and reticulated and may have 1 or 2 nucleoli, occasionally 3. There are no granules. The cells are oxidase-negative, and Auer bodies are never found. Some lymphoblasts resemble reticulum cells somewhat, whereas others resemble myeloblasts and have a nucleus with a delicate chromatin pattern. This form is frequently seen in acute leukemia. Atypical forms with lobulated, indented, and folded nuclei have been described as **Rieder cells.** Similar forms also occur in lymphocytic leukemia.

Lymphocytes: Lymphocytes are found normally in the circulating blood in the proportion of 21-30/100 leukocytes. Some authorities consider 35% lymphocytes a normal finding. They have been grouped as large and small lymphocytes, the large lymphocytes comprising about 6% of all the blood leukocytes. They are increased in thyrotoxicosis. The cytoplasm varies from very pale, almost invisible, clear light blue to deep blue, always clear. The width of the cytoplasm varies from a very narrow band to a very broad, smooth cytoplasm. Occasionally no cytoplasm is visible. There is usually an unstained perinuclear zone clearly visible. The nucleus is always stained deep blue or violet. It may show a deep-staining chromatin structure although the general appearance is smooth. It may be round, oval, or indented. It may be central or eccentric. Sometimes the nucleus shows distinct lobulation or segments (**Rieder forms**). These forms are pathologic. There are no granules, although azurophilic stippling is not uncommon. There is some evidence that increased gamma globulin is related to the production of these granules.

In the discussion of monocytes, mention has been made of transitional forms which combine features of lymphocytes, plasma cells, and reticulum cells as seen in macroglobulinemia or in virus diseases such as infectious mononucleosis and hepatitis. These cells are called **virocytes** or **atypical lymphocytes.** The older term of Türck's irritation cell also refers to an atypical lymphocyte of infectious origin, with dark blue cytoplasm and an eccentric nucleus.

In lymphocytic leukemia many abnormal forms appear, such as smudged cells (basket cells), spindle-shaped cells, naked nuclei, and the previously mentioned Rieder cells. By specialized method, such as supravital staining, phase microscopy, and electron microscopy, various cytoplasmic inclusions can be seen in lymphatic leukemic cells. These inclusions are of lipid, mitochondrial, and crystalline nature.

Wiseman, in attempting to evaluate the age of lymphocytes, studied normal adult human and rabbit bloods. As a result of his research, he stated that basophilia is manifestly a criteron of youth, but the absence of it in a given cell does not necessarily mean that the cell is mature.

For a description of lymphocytes in infectious mononucleosis, see p. 1332.

Plasma cells: Plasma cells are rarely found in the circulating blood in health. The cytoplasm stains intensely blue, with a fine reticular blue structure often showing vacuoles. The nucleus is usually eccentric and is surrounded by an unstained clear perinuclear zone.

In the bone marrow, plasma cells often have 2-4 nuclei. The cytoplasm may show inclusions, such as crystals, hyaline droplets, and Russell bodies. The last are protein (or paraprotein) structures derived from mitochondria as provided by electron microscopy. The mitochondria of the plasma cell are probably responsible for the production of gamma globulin. Electron microscopy reveals a well-developed ergastoplasm.

Megakaryocytes and blood platelets

Megakaryocytes are giant bone marrow cells never seen in the blood stream in health and very rarely found in the blood stream in disease. They are seen pathologically in the spleen and in the lungs, though a few can be found in both organs under normal conditions. They are very large finely granular faintly colored cells. The cytoplasm is pale blue or lavender. The nuclei show bizarre, antlerlike deep lobulations; they contain 1, 2, or more, sometimes as many as 12, of these nuclei. They are covered with a faint azurophilic dust.

Megakaryocytes are rarely found in the circulating blood. Megakaryocytes or megakaryocytic fragments have been seen in leukoerythroblastosis, myelocytic leukemia, erythremia, and Hodgkin's disease, in cases in which leukocytosis was present due to infection, and in all forms of myeloproliferative syndrome.

Megakaryoblasts: These are cells about twice the size of myeloblasts with a blue nongranular cytoplasm and a large, somewhat irregular single nucleus, which at times is kidney-shaped, with numerous nucleoli which cannot be seen with Wright stain but require special stain. These cells do not produce platelets. In normal preparations they comprise less than 1% of all the megakaryocytes.

Promegakaryocytes: These cells are usually about the same size as the megakaryoblast, although occasionally much larger, with scant dark blue cytoplasm and a dense nonlobulated or partly lobulated nucleus with heavy chromatin. These forms frequently have plateletlike bodies at the periphery of their cytoplasm and rarely nongranular cytoplasmic processes. Normally, promegakaryocytes make up about one third of the total number of megakaryocytes. They are especially numerous in the bone marrow of infants.

Adult megakaryocytes: This cell is of variable size, but is usually very large, and contains a single large multilobed nucleus, with increasing density as it matures. The cytoplasm varies in color from blue to pink and contains a variable number of characteristic azurophilic granules grouped at first in the perinuclear zone. Typical platelets which are almost always granular are frequently found in pseudopod-like structures grouped in masses about the periphery of the cell. The distribution of these cells in the normal bone marrow is uneven and depends somewhat on the technic used. There should be 1-3 megakaryocytes per low-power field of bone marrow smear. In bone marrow sections, the number appears to be increased, but the distribution can be judged more easily.

Degenerated forms: In these cells the cytoplasm is either homogeneous and hyaline in appearance, there is marked vacuolization of the cytoplasm, or the nucleus is hyperlobulated and its cytoplasm is nongranular. Frequently naked degenerative megakaryocytic nuclei can be seen surrounded by platelets. Polykaryocytic forms of megakaryocytes cannot be easily separated from osteoclasts. Such forms are seen in pernicious anemia and in idiopathic thrombocytopenic purpura.

It must be recognized that the relationships of the various types of cells to each other may be more artificial than real since they are based on a study of what appears to be transition forms. Because of this uncertainty, the megakaryoblasts and promegakaryocytes may be designated young forms and the adult types adult forms, with a separate designation for the degenerated cells.

For further information, see the discussions of platelets and idiopathic thrombocytopenic purpura.

Nonhematologic cells found in film of peripheral blood

Three groups of cells may be found: (1) fungi (*Histoplasma capsulatum* in monocytes), (2) parasites (malaria and *Bartonella* in red blood cells), and (3) tumor cells.

The first two will be considered in the discussion of hemolytic anemia.

Tumor cells in peripheral blood[228-231]: Since carcinoma spreads by lymphatic and hematogenous routes, tumor cells may be found in the peripheral blood film. Because the finding of tumor cells in the routine peripheral film is rather unusual, methods have recently been developed to concentrate the tumor cells circulating in a given quantity of blood. These methods utilize Millipore* filters and enzymes. The presence of cancer cells in the peripheral blood may warn the physician that even after successful surgery the patient will require some other type of therapy. At the present time these concentration methods are somewhat tedious and probably somewhat inadequate because of the small size of the blood sample (5-10 ml.) and because of the difficulties in recognizing circulating cancer cells. It may well be that the Millipore filter technic in conjunction with the acridine orange fluorescent technic will give better results.

METHODS OTHER THAN WRIGHT OR WRIGHT-GIEMSA USED IN STUDY OF BLOOD MORPHOLOGY

The cell description contained in the preceding pages refers to blood cells stained with Wright, Giemsa, or Wright-Giemsa stains.

In recent years new methods have been utilized to discover the finest details of blood cell morphology, or older methods have been adapted and modified for similar purposes.

Dark-field examination

Dark-field examination is based on the fact that objects which are illuminated by oblique light which is not allowed to enter the objective will reflect and scatter the light rays. They thus appear brilliant against a dark background.

If unstained blood is examined with the dark-field microscope, the white cells are difficult to recognize, with the exception of the eosinophils and basophils which contain prominent granules. The erythrocytes are seen as pale yellow disks. For the investigation of reticulocytes and Heinz bodies, dark-field examination after supravital staining is satisfactory. It is equally applicable to the examination for basophilic stippling. Dark-field examination allows the visualization of platelets and of numerous plasma structures of doubtful significance.

Phase microscopy

Phase microscopy allows the observation of unfixed living cells without any prior treatment. Phase microscopy transforms differences in the refractive index of the various cell structures into degrees of brightness and contrast. It thus allows the observation of living mitochondria and other intracytoplasmic structures. Outstanding contributions to the subject of hematology and phase microscopy will be found in the papers of Bessis,[232] Ackermann, and Bellios.[233]

---

*Millipore Filter Corp., Bedford, Mass.

Description of most important cells as they appear in phase microscopy

Neutrophils: These cells measure 12-18μ in diameter. The cell has ameboid movement. The nucleus is dense and is surrounded by cytoplasm which shows intracytoplasmic movement, specific granulation, and phagocytosing vacuoles. The myeloid precursor form shows nucleoli and numerous mitochondria.

Lymphocytes: The nucleus shows a dense chromatin pattern interrupted by a small nucleolus. The cell shows movement in which the nucleus precedes the cytoplasm. The latter is seen to contain mitochondria.

Monocytes: The nucleus has a delicate chromatin pattern and frequently contains 1 or 2 small nucleoli. The cytoplasm contains mitochondria and during movement produces flat, broad pseudopods.

Erythrocytes: If red cells contain Howell-Jolly bodies or Heinz bodies, these can easily be seen with phase microscopy. The nucleus of erythroblasts contains nucleoli, and the cytoplasm contains perinuclear mitochondria. The dense normoblastic nuclear chromatin pattern can also be seen.

Platelets: The pseudopodia and the division into hyalomere and granulomere can easily be seen when platelets come in contact with a surface. Phase microscopy is the basis for one of the best methods of platelet counting.

Fluorescent microscopy

Fluorescent microscopy allows recognition of substances within tissues by their ability to fluoresce. When these substances are exposed to invisible ultraviolet light of short wavelength, they absorb this light and are thus excited. In this excited state they emit visible rays of light. Some tissues fluoresce naturally, whereas others fluoresce only after staining with certain dyes (primary and secondary fluorescence).

Fluorescent technic is extremely sensitive and is able to detect dye concentrations in the order of $1:10^{-18}$.

In erythropoietic porphyria, fluorescent erythrocytes and erythroblasts can be seen (**fluorescytes**). Similar cells in small numbers have been reported in untreated pernicious anemia. Fixed bone marrow and blood films can be stained with acridine orange and coriphosphin O. In the erythroid series the more mature a nucleus, the more brilliantly will it be stained, whereas the cytoplasm stains more vividly the younger the cell is; i.e., the less hemoglobin it contains. Heinz bodies can be recognized under ultraviolet light in the air-dried preparation. As far as the white cell series is concerned, living leukocytes have a delicate primary fluorescence which increases as the cells die. Fluorescent microscopy, as well as phase microscopy, has been used to show the production of platelets from megakaryocytes.

Electron microscopy

Electron microscopy allows two approaches—magnification up to 200,000 times

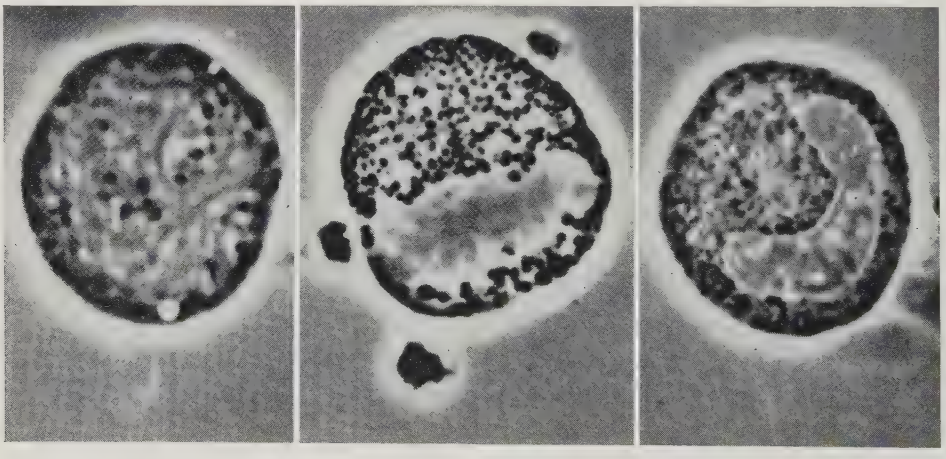

Fig. 389. Phase contrast photomicrographs of granulocytes. **A,** Neutrophil. **B,** Eosinophil. **C,** Basophil. (From Bernard, J., and Bessis, M.: Hematologie clinique, Paris, 1958, Masson & Cie.)

of sections cut at 0.02μ thickness and magnification up to 1000 times of unstained cells.

Erythrocytic series: Bessis and others investigated normal and abnormal red blood cells and found that the surface of a normal red cell shows a few craterlike depressions. Under the influence of hemolytic substances, these craters increase in depth, and the surface becomes irregular. The surface of the reticulocyte is very irregular, with numerous folds, craters, and fissures. The investigation of the stroma of the red cell exposed to a hemolytic system shows movement of the residual hemoglobin from the periphery of the cell to its center. Studies of iron metabolism show beautifully the destruction of red blood cells within phagocytes, the liberation of ferritin, the transfer of the phagocytosed ferritin from the reticulum cell to the erythroblast by the process of pinocytosis, and finally the transformation of the ferritin into erythroblastic mitochondria. Later in the development of the cell, this iron is again liberated and is incorporated into the hemoglobin molecule.

Leukocytic series: The nuclear pattern depends on the chromatin contents. The nucleus is surrounded by a cell membrane and contains a darker nucleolus. Electron microscopy allows the visualization of mitochondria. Each mitochondrion is surrounded by a membrane carrying cristae on its side. The granulations of the various leukocytes vary somewhat in appearance according to their age and type. Many of the intracytoplasmic structures such as the Golgi apparatus and the centrosome have been investigated.

Under pathologic conditions changes have been seen in nuclei, in mitochondria, and in intracytoplasmic structures. The bone marrow cells have also been investigated, and most of the work on the transport and utilization of ferritin has been done on bone marrow preparations. Electron microscopic investigation of the megakaryocyte shows its cytoplasm to contain small canaliculi which surround small cytoplasmic areas so that the cytoplasm has a definite fielden pattern somewhat reminiscent of platelet formation within the cytoplasm.

Making and staining thick drop preparations

The thick drop method of examination of blood is an important procedure in searching for parasites.

Parasites of malaria, filaria, trypanosomes, etc., may be found more readily in the thick drop than in the blood film. Often these parasites may be seen in the thick drop but not

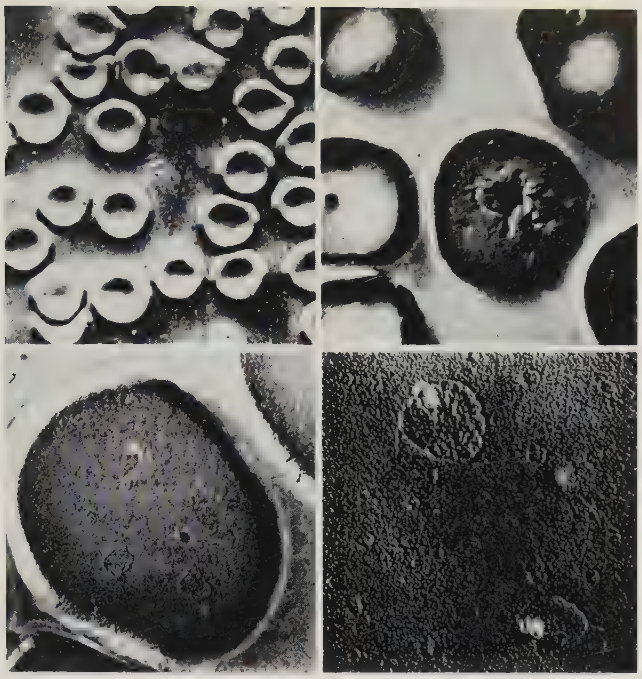

Fig. 393. Electron micrographs of normal red blood cells showing craterlike depressions. Although they may be artifacts, they are related to the integrity of the red blood cells; e.g., after exposure of the cell to antierythrocytic antibodies these craters become wider, deeper, and more numerous. (From Bernard, J., and Bessis, M.: Hematologie clinique, Paris, 1958, Masson & Cie.)

in the spread. The reason for this is that every field in the thick drop preparation is equivalent to 50 fields in the spread. Thus examining 4 fields in the thick drop is equal to examining 200 fields in the spread. The erythrocytes are dissolved by the water in the diluted Giemsa stain, making it easy to see blood parasites and structures of young erythrocytes. The eosinophils are very definite, the granules being bunched together. Basophils appear as a group of fibrin needles around a circular solidly stained center, the whole structure being stained purple-red. Neutrophils are typical, except that the cytoplasm has dissolved. The nuclei and granules, however, remain. In other words, all substances in the blood that are soluble in water are dissolved in the thick drop staining process. The other structures remain as they are.

Procedure:

1. Place 2 drops blood on a glass slide.
2. Spread the 2 drops in a circle to 3 times the original diameter of the drops.
3. Allow to dry thoroughly either in an incubator (after preliminary drying in the room) for ½-3 hr. or at room temperature. Do not leave it in bright sunlight or anywhere where dust may settle on the slide. **Do not fix.**
4. Place the slide on a staining bridge. Gently cover with Giemsa stain, taking care not to dislodge the drops from the slide.
5. Allow the diluted stain to remain in contact with the drops of blood for 3 min. or until the hemoglobin begins to dissolve. This can be detected by holding a piece of white paper under the slide. The hemoglobin will be seen flowing through the diluted stain. Then gently tilt the slide and allow the stain to drain off. Re-cover with diluted Giemsa stain, taking care not to dislodge the drops of blood.
6. Stain for 30 min.
7. Remove the stain by gently tilting the slide.
8. Wash very carefully with neutral distilled water so as not to remove the blood drops from the slide and allow to dry by standing the slide on end. **Do not blot.**
9. Examine with the oil immersion objective.

Modified method of staining thick drops for examination for malarial parasites[234]*

1. Mix Giemsa stain with buffer solution pH 7.0-7.2 or neutral distilled water in the proportion of 1 drop Giemsa stain for each 2 drops buffer. Mix in a test tube or small cylinder.
2. Place just enough stain on the thick drop to cover it and allow to remain for 3 min.
3. Wash either by immersing in a jar of neutral distilled water or in the usual manner of washing a slide.

Combined thick drop-thin film method (Agress modification)

1. Place a drop of blood on one end of a glass slide and spread to about 2 or 3 times its diameter in a circular manner, using the puncture point or the corner of another glass slide.
2. Make a thin spread of blood on the rest of the slide in the standard manner.
3. Separate the area of the thick drop and the thin spread by drawing 2 or 3 lines between them with a wax pencil.
4. Either place the slide in a 37° C. incubator for ½ hr. or allow to remain at room temperature for 1 hr.
5. Add Wright stain for 2 min. to the thin spread **only.**
6. Dilute with neutral distilled water or buffer for 2 min., taking care that this stain does not run over onto the thick drop.
7. Pour off.
8. Flood the entire slide including the thick drop with diluted Giemsa stain (freshly prepared, using 1 drop stock Giemsa stain to 3 ml. neutral distilled water or buffer solution).
9. Allow to remain on the slide for 30 min.
10. Wash and air dry.

Direct count of eosinophils in blood

The routine differential count is usually sufficient to determine the relative number of eosinophils in the blood. On the basis of the total white cell count and the differential count, the number of eosinophils per c.mm. can be calculated, but for certain clinical purposes an absolute eosinophil count made in a counting chamber is preferable. There are 2 types of diluting fluid. An example of one is the Friedman solution which contains eosin to stain the granules, acetone as a fixative of leukocytes, and distilled water to lyse the erythrocytes. The second type, which is usually a modification of the Randolph fluid,[236] uses eosin or phloxine as acid dye, propylene glycol to lyse the red cells, sodium carbonate as accentuator, and heparin to prevent clumping of the white cells.

Method of Friedman[235]

Reagent:

Aqueous eosin, 1%	5 ml.
Acetone	5 ml.
Distilled water	100 ml.

Procedure:

1. Dilute the blood in the usual manner in a white blood counting pipet, using the Friedman reagent as the diluting fluid. The diluting fluid stains only the eosinophilic cells, which are easily distinguishable with the high dry power lens of the microscope. The unstained leukocytes appear as gray bodies in this diluting fluid.
2. Count the eosinophils in all 9 large squares of

---

*This is the method used at the Ryder Memorial Hospital, Humacao, Puerto Rico.

2 chambers and repeat the count with a second pipet.

Calculations: See method of calculation described for Method 2.

Method 2

Reagent:

Propylene glycol	50 ml.
Distilled water	40 ml.
Aqueous phloxine, 1%	10 ml.
Aqueous sodium carbonate, 10%	1 ml.
Heparin sodium	100 units

Procedure:

1. Draw blood to mark 1 (top of the stem) in a white counting pipet.
2. Draw the diluting fluid into the pipet until a total of 11 vol. is reached. The dilution of the blood is 1:10.
3. Shake well.
4. Let stand for 10-15 min.
5. Again shake well, let out a few drops, and fill both sides of the counting chamber as usual.
6. Let stand in the counting chamber for 3 min.
7. Count under the low power with the condenser in place. Adjust the light by **slightly** lowering the condenser until the maximum number of white cells is seen and the eosinophils appear as very tiny red stained cells. The eosinophilic granules are brilliant red.
8. Count all the eosinophils in the entire 9 fields of the counting chamber (9 sq.mm.).
9. Count the eosinophils in the counting chamber on the other side of the hemocytometer in the same way and calculate the average of the two counts.
10. Multiply the average by 11 to obtain the number of eosinophils in 1 c.mm. blood. (Dilution of blood is 1:10, area counted is 9 sq.mm., depth of the counting chamber is 1/10 mm. The volume counted is $1/10 \times 9 \times 1/10 = 9/100$ or approximately 1/11 c.mm.).

To obtain per cent of eosinophils: The % of eosinophils is the eosinophil count per c.mm. divided by the white blood cell count per c.mm.

Report the count made in the counting chamber as the absolute count and the percentage as indicated.

Example:
Patient's white count: 8163/c.mm.
Eosinophils: 276/c.mm.
276 : 8163 = 0.03 or 3%.
Normal: 2-4%; 150-300/c.mm.; average, 200.

Thorn test

The blood eosinophil response to the injection of pituitary adrenocorticotropic hormone (ACTH) or epinephrine is the basis of the Thorn test[237] of adrenal cortex function. In normal subjects, such injections are followed in 4 hr. by a fall in the total blood eosinophil count of over 50%. In patients with Addison's disease, the decrease in eosinophils is 20% or less. In patients with adrenal insufficiency secondary to pituitary disease, the injection of epinephrine is followed by no significant change in the eosinophil count, but injection of ACTH produces a normal decline in eosinophils.

This screening procedure is performed with the patient starting in the fasting state and remaining so throughout the 4 hr. period of observation. A total blood eosinophil count is performed, and then 25 mg. ACTH or 0.3 ml. 1:1000 dilution of epinephrine is injected intramuscularly. Four hours later another eosinophil count is performed, and this value is compared with the original count.

This test is merely a screening test. An attempt is made to stimulate the adrenal cortex by administration of either epinephrine or adrenocorticotropic hormone. Changes in the circulating eosinophil count are accepted as indicators of adrenal cortical function. After the intramuscular administration of 0.3 ml. epinephrine hydrochloride, the healthy anterior pituitary releases adrenocorticotropic hormone (ACTH) which stimulates the adrenal cortex, thus increasing the output of its steroids. A maximal decrease of circulating eosinophils will be noted 4 hr. after the injection. If the pituitary pathway is not to be included, ACTH may be administered directly, either 25 units I.M. or 50 units in 500 ml. normal saline intravenously over a period of 8 hr. This procedure may be repeated the next day. The responsive adrenal will increase its steroid output.

In addition to the eosinophil count, the urinary corticoids before and after ACTH or epinephrine administration should be examined. The most important of these corticoids are the 17-hydroxysteroids.

Chapter 63

Coagulation of blood and hemorrhagic diseases

JOHN D. BAUER

Hemostasis, the arrest of bleeding, depends on 2 main factors: structurally and functionally intact blood vessels and adequate blood coagulation. Inadequate blood vessels are more frequently the cause of bleeding than defects in coagulation. The onset of bleeding is always associated with a faulty vascular system, whereas a defective clotting mechanism is responsible for the continuation of the bleeding. The patient with afibrinogenemia, whose blood does not clot, does not bleed until a blood vessel is injured. The freely flowing blood within blood vessels is the result of an equilibrium established by the various clotting factors and their antagonists. Coagulation defects occur when there is a decrease in coagulation factors or an increase in inhibitors (hypocoagulability), whereas an increase in coagulation factors and a decrease in inhibitors may lead to hypercoagulability. This equilibrium between coagulation factors and inhibitors is of the greatest importance in the production of thrombosis of blood vessels, a phenomenon which in its importance by far exceeds the problem of bleeding tendency.

THEORIES OF BLOOD COAGULATION AND LABORATORY ASPECTS OF HEMOSTASIS

Historical review

The ferment theory was first advanced by Alexander Schmidt.[238] He emphasized that the specific ferment for blood coagulation was thrombin, a product which occurred with the breaking down of the corpuscular elements of the blood, especially the leukocytes. A schematic representation of the Schmidt ferment theory is shown in Fig. 396.

It was Hammarsten[239] who introduced the question of the role of fibrinogen into blood coagulation. Arthus and Pages[240] first called attention to the calcium content of the blood as of prime importance in blood clotting. They noted that the addition of oxalates to blood, which made it calcium-free, prevented clotting and that the re-addition of calcium produced clotting. Pekelharing[241] made further researches into this calcium factor. Hammarsten claimed that the presence of calcium is necessary before prothrombin could be activated into thrombin. Fuld[242] and Spiro[243] showed that 3 substances, which are precursors of thrombin, are necessary for blood clotting: namely, the thrombogen of Morawitz, the plasmochyme of Fuld, and soluble calcium salts. Another substance which Morawitz introduced into the literature was thrombokinase, which Fuld called cytozyme. Fig. 397 illustrates Morawitz' ideas on blood clotting.[244]

Howell[245-249] is responsible for the present-

day understanding of the phenomenon of blood coagulation.

Prothrombin + Ca ions + Thromboplastin = Thrombin
Thrombin + Fibrinogen = Fibrin

Within the past 20 years, interest in blood coagulation has been greatly stimulated, and as a result a voluminous literature concerning hemostasis has been accumulated. As new facts have been disclosed, theories of blood coagulation have been modified and amplified.

Present concept of coagulation

The ultimate aim of blood clotting is the formation of fibrin. The fibrin formation is accomplished by the interaction of 2 systems—an intrinsic system, in which only factors present in the blood itself take part, and an extrinsic system, in which tissue factors, such as tissue thromboplastin, also take part.

The external system which has to do with the initiation of the clotting mechanism does not require platelets and factor VIII but needs factor VII and factor V. The intrinsic system which is responsible for the definite hemostasis does not require factor VII but needs all other factors which take part in phase 1 of clotting. Both systems require factor V and Stuart-Prower factor and calcium. After the formation of 1 or 2 intermediate products (blood and tissue convertin ?), both processes, the intrinsic and the extrinsic, follow a similar pathway to the formation of fibrin.

The clotting factors are enumerated in Table 240.

Table 240. *Clotting factors**

Assigned number of clotting factor	*Synonymous names*
I	Fibrinogen
II	Prothrombin
III	Tissue thromboplastin
IV	Calcium
V	Labile factor; accelerator globulin; proaccelerin
VI	Accelerin; accelerator globulin
VII	Stable factor; proconvertin
VIII	Antihemophilic factor; AHF Antihemophilic globulin; AHG Thromboplastinogen
IX	Plasma thromboplastin component; PTC Christmas factor
X	Stuart factor; Stuart-Prower factor
?	Plasma thromboplastin antecedent; PTA
?	Hageman factor; HF
?	Platelet factors 1-8, such as serotonin, antifibrinolysin, retraktozyme, fibrinogen and factor V-like substances, antiheparin, and thromboplastinogenase

*From Bauer, J. D., Toro, G., and Ackermann, P. G.: Bray's clinical laboratory methods, St. Louis, 1962. The C. V. Mosby Co.

Coagulation can be visualized as occurring in 3 stages. The first phase is concerned with the production of plasma thromboplastin. In this reaction, the following factors are involved: platelets (mainly platelet factor 3), plasma factors VIII and IX, PTA factor, Hageman factor, Stuart-Prower factor, Quick's erythroid factor, and calcium. Spittel recently described a temporary pathologic plasma factor which has an accelerating influence on plama thromboplastin formation, and if it is confirmed, it may be of considerable clinical importance. The intrinsic thromboplastin is labile and disappears within 1 hr. In the process of clotting, factors VIII and V are consumed and may thus be considered to be substrates for enzymes. Factors IX and VII are not consumed and are probably the enzymes acting on the substrates just mentioned.

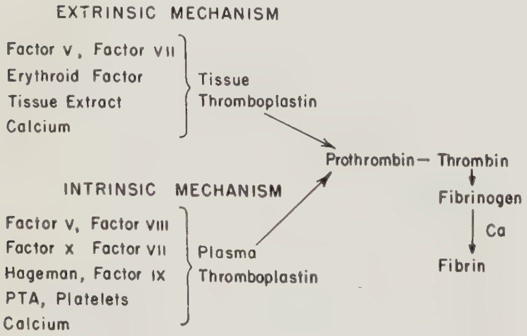

Fig. 398. Diagram of blood clotting. (From Bauer, J. D., Toro, G., and Ackermann, P. G.: Bray's clinical laboratory methods, St. Louis, 1962, The C. V. Mosby Co.)

The second stage of coagulation is the conversion of prothrombin to thrombin through the action of plasma thromboplastin generated in the first stage. For the conversion of prothrombin to thrombin by tissue thromboplastin, a phospholipid (probably cephalin), calcium, and factors VII and V are necessary. The nature of the conversion of prothrombin to thrombin is not known but probably involves splitting off portions of the original prothrombin molecule. Thrombin is normally not present in the circulation.

The third phase is the conversion of fibrinogen to fibrin with the help of thrombin produced in the second stage. The result of fibrin formation is the clotting of blood. Thrombin, a proteolytic enzyme, splits off glutamic acid containing portions of the fibrinogen molecule. In the freely flowing blood the stability of fibrinogen, a protein of high molecular weight, in solution is apparently due to negatively charged terminal groups which include glutamic acid. After the glutamic acid-containing portions are split off, the remaining segments of the original fibrinogen molecule are called fibrin molecules. These fibrin molecules are attracted to each other by electrostatic forces and polymerize by end-to-end and side-to-side apposition to produce visible fibrin fibers. After the fibrin clot is formed, it retracts, and after a certain period of time it is dissolved by the fibrinolytic system of the blood. The clot retraction is essentially a function of platelets which undergo viscous metamorphosis, thus apparently releasing a factor called retraktozyme.

According to recent investigators,[250] glucose, divalent cation, and a critical pH are also required.

Each phase is subject to the action of inhibitors. These substances which help to maintain the blood in liquid state are of great physiologic importance. They are responsible for the disappearance of coagulation factors which may be formed in excess. If they occur in abnormal amounts or types, they may lead to a bleeding tendency.

Inhibitors of phase 1: Antithromboplastin (Tocantins), antifactor VII factor, when present in excess is thought to be responsible for some cases of hemophilia. A circulating anti-tissue-thromboplastin may also exist (Stefanini and Dameshek). This will be discussed in the section on immunohematology.

Circulating inhibitors may be the result of transfusions, pregnancies, or allergies or may accompany certain diseases such as collagen diseases. In phase I circulating anticoagulants may prevent the formation of thromboplastin, but they do not act on already formed thromboplastin or thrombin. Inhibitors to factor VII and factor V have been described. The activity of heparin, which is mainly an antithrombin, also extends into phase I since it has some antithromboplastic and antiplatelet action (serotonin).

Inhibitors of phase 2: Several types of antithrombin occur normally in the plasma and serum. Antithrombins V and VI have been considered responsible for bleeding tendencies. Heparin, a mucopolysaccharide produced by blood and tissue basophils (mast cells), acts as an antithrombin by combining with a heparin cofactor and thrombin (antithrombin II). Fibrinogen (antithrombin I) by its ability to adsorb thrombin also acts as an antithrombin. Seeger antithrombin III acts without the help of heparin.

Inhibitors of phase 3[251, 252]**:** The main inhibitor is fibrinolysin, the end product of a fibrinolytic enzyme system. The naturally occurring fibrinolytic enzyme precursor is called plasminogen. In the presence of activators (kinases) it is converted into a trypsinlike proteolytic enzyme, fibrinolysin, which hydrolyzes fibrin at neutral pH. The kinases involved may be naturally occurring such as tissue kinases, trypsin, plasmin, and urobinase (urine), or they may be bacterial in origin such as streptokinase and staphylokinase.

Properties of clotting factors

Most clotting factors are alpha and beta globulins, produced by the liver. They have a half-life in the circulating blood of from a few hours to a few days. As will be shown later, deficiency in clotting factors may be either congenital or acquired.

Factor I (fibrinogen): Fibrinogen is a soluble circulating protein which is not present in serum and is precipitated by 23-45% ammonium sulfate. In the electrophoretic field it moves with the beta and gamma globulins. It is formed in the liver and probably in the bone marrow and is the precursor of fibrin. A level below 100 mg./100 ml. plasma is indicative of hypofibrinogenemia. The congenital or acquired absence or the diminution of fibrinogen will be considered in the discussion of hemorrhagic diseases. Fibrinogen is increased in several conditions such as pregnancy, infectious diseases, myocardial infarction, rheumatic fever, and old age.

Factor II (prothrombin): Prothrombin is a glycoprotein with alpha globulin motility in the electrophoretic field. It is precipitated by 50% ammonium sulfate and is normally present in plasma. It is consumed in the clotting process so that the normal serum contains only a trace. Vitamin K_1 is essential for the production of prothrombin by the liver and perhaps by the lung. Vitamin K_1 is a coenzyme which the liver utilizes for the formation of prothrombin and factor VII. Acquired and congenital hypoprothrombinemia are included in the discussion of hemorrhagic disorders.

Prothrombin is converted to thrombin by the action of thromboplastin. In this process it loses 2 amino acids and its carbohydrate fraction. The most common prothrombin deficiency is produced therapeutically by the administration of Dicumarol, which is a powerful anticoagulant.

The structural formulas of Dicumarol and vitamin K_1 are so similar that it is felt that Dicumarol acts by replacing the prosthetic group of the hepatic enzyme which utilizes vitamin K_1 in the production of prothrombin and factor VII. Administration of Dicumarol produces factor VII deficiency and to a lesser degree depression of prothrombin and factors IX and X. The effect of Dicumarol administration can be counteracted by the administration of vitamin K_1 (liver function must not be impaired). Because of the described action of Dicumarol, patients on this type of anticoagulant therapy will show not only an abnormal 1-stage prothrombin time, but also an abnormal thromboplastin generation test. As Dicumarol is detoxified in the liver and excreted by the kidneys, diseases of these 2 organs will markedly alter the results of Dicumarol therapy.

In the first week of life the prothrombin level is low (even more marked in premature babies—danger in circumcision).

Factor III (thromboplastin): Thromboplastin is required for the conversion of prothrombin to thrombin. We distinguish 2 types, as indicated in Fig. 398: (1) tissue thromboplastin, which acts in seconds and requires for its formation tissue extract, probably phospholipids, and factors V, VII, and X, and (2) plasma thromboplastin, which requires several minutes for production and needs the following factors: Hageman, V, VIII, IX, X, PTA, platelets, and calcium. Both thromboplastins can be activated by plasma and serum.

Factor IV (calcium): Calcium ions, though admittedly in very low concentrations, are necessary for the formation of thromboplastin. In vitro, the removal of calcium is the basis of the most commonly used laboratory anticoagulants. In vivo, the removal of calcium must be counteracted if citrated blood is used instead of heparinized blood in massive transfusions or in exchange transfusions.

Factor V (labile factor): Factor V is labile and is activated by thrombin to factor VI. It is consumed during clotting and is not affected by Dicumarol. Inactivated by heating to 58° C., it is precipitated by 33% ammonium sulfate. It is a proenzyme, activated by a plasma factor, and functions as a thromboplastin cofactor. It is lost in stored oxalated plasma and is not found in serum.

Factor VI (accelerin): Factor VI is a tissue thromboplastin cofactor and is produced either in the liver or during the conversion of prothrombin to thrombin.

Factor VII (stable factor): Factor VII is a plasma factor which is not lost in stored oxalated plasma. It is not consumed during clotting and is thus present in serum. It is produced in the liver with the aid of vitamin K_1. It is often deficient in the neonatal period. Factor VII is affected by the administration of Dicumarol and related drugs.

Factor VIII (antihemophilic factor): Factor VIII is a beta globulin which is stable for 5 min. at 38°-49° C. at a pH of 6.8. It is produced by the reticuloendothelial system and is necessary for thromboplastin formation in plasma. Factor VIII is probably produced in the liver, lungs, and kidneys, and its production is related to the hemophilia chromosome (sex-linked). In the absence of factor VIII, platelet factor I may be part of an alternate pathway of activation of prothrombin. Factor VIII is consumed during the clotting process (see discussion of hemophilia and hemorrhagic disorders) and is thus not present in serum. Though labile it can be preserved in citrated plasma at 20° C. and in lyophilized form.

Factor IX (plasma thromboplastin component): This factor occurs in plasma and serum, probably in an inactive form.

Factor X (Prower-Stuart factor): This factor is similar to factor IX and is involved in thromboplastin production. It is present in plasma and serum.

Plasma thromboplastin antecedent (PTA): This is a factor present in plasma and serum and is stable during blood storage.

Hageman factor: This factor, which is activated by glass, is necessary for the development of blood thromboplastin. It may also have some relationship to capillary permeability.

Platelets: Platelets are involved in the initiation of blood clotting, which is considered in the discussion of the mechanism of coagulation.

Mechanism of coagulation

After injury the smaller blood vessels contract and retract. The contraction is aided by platelets which release a vasoconstricting agent, serotonin. The release of this and other platelet factors is apparently related to viscous metamorphosis of platelets. The endothelial lining of the blood vessels becomes sticky so that opposing surfaces adhere to each other. The endothelial change may be related to electrostatic changes so that the negative endothelial cells attract positive platelets. There may well be several ways by which blood clotting is initiated. The platelets which show viscous metamorphosis become sticky and adhere to the vessel wall. A plasma factor may be helpful in the production of this stickiness and adhesiveness of the platelets. On the other hand, Quick believes that a minute amount of fibrin may activate the plasma factor, which in turn acts upon the platelets so that they disintegrate. At one time factor VIII was believed to be the activating plasma factor. Quick describes an erythrocytic clotting factor which is released when the red cells come in contact with a foreign surface.

The initiation of clot formation may be related to the release of tissue thromboplastin at the time the blood vessel is injured. Thromboplastin reacts with prothrombin to form a small amount of thrombin which in turn will not only produce a small amount of fibrin, but will also act upon platelets, stimulating them to release platelet factors. On contact with glass the interaction of the Hageman factor and the Quick erythrocytic factor apparently initiates clotting. Immediately after injury, the external system of blood clotting is called into play, and whether an intermediate product (such as convertin) is involved or not, there is a slow conversion of prothrombin to thrombin by tissue thromboplastin. The small amount of thrombin thus formed activates factor V and in the presence of calcium the conversion of prothrombin to thrombin. As this process continues, the production of thromboplastin increases in speed. Thrombin then acts on fibrinogen to produce fibrin. This process is dependent on the concentration of fibrinogen, on the pH, on the temperature, and probably also on platelet action.[254] It is evident that coagulation is the result of interplay of actions and counteractions so that at each step the rate of production of the clotting product must exceed the rate of formation of the inhibitor. Coagulation thus consists of an action not unlike that of a pinwheel in a Fourth of July fireworks display. There is the slow starting outer phase (thromboplastin to minimal prothrombin conversion), a sputter (thrombin formation), a high-speed brilliant phase with sparks flying in all directions (thrombin activating accelerators, thrombin labilizing platelets, more prothrombin being converted, fibrinogen being converted to fibrin), and then the slowly dying-out phase (a firm clot being formed and fibrin slowly applying the brakes).

TESTS FOR HEMORRHAGIC DISEASES

The investigation of the bleeding patient must include (1) good history with special attention to previous bleeding episodes, allergies, infections, family history, and liver disease, and (2) inspection and examination of the patient with special attention to the skin, to the presence of petechiae (thrombocytopenia), ecchymoses (coagulation defect), and to mucous membranes such as gums. The size of the liver, spleen, and lymph nodes may offer possible clues to the disease.

As will be discussed later, the hemorrhagic diseases include 3 main groups of defects: (1) vascular defects, (2) coagulation defects, and (3) platelet defects. In order to evaluate all 3 and despite some overlap, coagulation tests should follow a given order:

1. Tests for vascular function and capillary permeability, such as bleeding time and tourniquet test.
2. Tests for platelet function, such as clot retraction, platelet count, and bleeding time.
3. Tests for over-all clotting ability of the blood, such as clotting time.
4. Tests for phase III of the clotting mechanism, such as fibrinogen level.
5. Tests for phase II of the clotting mechanism, such as plasma prothrombin time.
6. Tests for phase I of the clotting mechanism, such as serum prothrombin time, and thromboplastin generation test.
7. Tests for circulating anticoagulants.

Collection of blood

General instructions for all coagulation tests: As in all laboratory tests, strict adherence to technic in every detail is necessary. Most tests should be performed at 37° C., the body temperature. Carefully cleaned, not scratched, 13 × 75 mm. test tubes are used in almost all the procedures. Pipets should be acid cleaned. Delays in completing the test should be kept at a minimum, as contact with glass tends to shorten the clotting process and standing at room temperature will destroy the thermolabile factors.

Siliconized glassware: Frequently in the following tests siliconized glassware will be mentioned.

Coating with silicone: The glassware must be clean, must be kept from dust when siliconized, and must be stored and cleaned separately from the rest of the laboratory glassware. For siliconizing, a mixture of 1 part Drifilm* and 4 parts petroleum ether are used.

Test tubes:

1. Fill 1 tube with silicone mixture to the top and then pour the mixture from 1 tube to the other, thus coating the tubes.
2. Fill coated tubes with distilled water and allow to stand for 5 min.
3. Rinse with distilled water 3 times.
4. Dry in an oven at 120° C. for 1 hr.

Adequacy of siliconization can be checked by half filling the tubes with water and observing the convex meniscus.

Pipets:

1. With a rubber bulb draw silicone mixture to a point close to the mouth end.
2. Empty.
3. Rinse with distilled water 3 times.
4. Dry in an oven at 120° C. for 1 hr.

Syringes: Coat the barrel by aspirating 3 ml. silicone mixture. Hold the syringe with the tip directed upward and pull the plunger up and down 3 times. Rinse the barrel and plunger repeatedly and dry separately in an oven at 120° C. for 1 hr.

Needles: Silicone coating of needles is not usually considered necessary if new needles are used for each puncture. If coating is required, the silicone mixture is aspirated through the needle and is then blown out by compressed air. Immerse the needle in ammonium hydroxide, dry, and clean the bore with a nylon bristle.

For special coagulation test, apply 6 coats of silicone and polish the siliconized surfaces after each coating with a nylon cloth.

Removal of silicone:

1. Wash glassware in warm water and then immerse in the following solution overnight.

Acetone, technical	2 L.
Distilled water	2 L.
NaOH (solid)	150 gm.

2. Dissolve the sodium hydroxide in about 300 ml. water before adding to acetone and water.
3. After immersion, rinse well and dry in an oven.

TESTS FOR STATUS OF CAPILLARIES

BLEEDING TIME

Method I—Duke[255]

Procedure:

1. Cleanse the ear lobe and make a cut, not a puncture, with a scalpel blade, needle, or Steri-Lancet, 3-4 mm. deep and approximately 5 mm. long, against a microscope slide held behind the ear lobe.
2. Touch a piece of blotting paper to the area every 30 sec., touching only the head of the drop. The test is terminated when no more free drops can be picked up on the blotting paper.

The bleeding time is measured from the moment the blood appears to the cessation of bleeding. Record the time with a stopwatch.

Normal: 1-3 min.

Method II—Ivy[256]

Materials:

1. Sphygmomanometer.
2. Sharp-pointed blade.

Procedure:

1. Place a blood pressure cuff on the arm and inflate to 40 mm. Hg.
2. Cleanse the volar surface of the forearm below the cuff and make a skin wound 3-4 mm. deep.
3. Blot the incision every 10 sec. until there are no more free drops, maintaining a pressure of 40 mm. throughout the procedure.

The bleeding time is measured from the moment the blood appears to the cessation of bleeding. Record the time with a stopwatch.

Normal: 0-4 min.[257]

Method III—Copley-Lalitch[258]

Procedure:

1. Cleanse the finger and make a puncture wound 6 mm. deep.
2. Immerse the wound in sterile physiologic saline warmed to 37° C. until there is no free flow of blood.

The bleeding time is measured from the moment of the wound to the cessation of bleeding.

Normal: In 95% of persons the normal values are less than 3 min. with a range of 170-340 sec.

Comments on skin bleeding time

The response of the skin capillary bed as measured by these tests is dependent upon many factors, such as skin turgor, adiposity and vascularity of subcutaneous tissue, and variations in technic, as well as upon the state of the blood vessels and the blood coagulation mechanism. Obviously, any test which attempts to measure so many variables can give information only of a general nature and serves only as a gross screening test.

Abnormally prolonged bleeding times are associated with thrombopenic states.

In a discussion on the mechanism of hemostasis, Macfarlane[259] called attention to the lack of capillary contractility associated with thrombocytopenic purpura. By visualization of the nail beds under the microscope, he noted differences in the capillary reaction in various conditions and particularly called attention to the abnormal reaction in thrombocytopenia. This reaction of capillaries is of such marked degree that it might be considered an integral part of the disease process. The extent of bleeding manifestation in cases of thrombocytopenic purpura is as directly related to the state of the capillary bed as it is to the platelet level. Although bleeding times and platelet levels usually parallel one another, there are cases in which the bleeding time may be prolonged, with only a slight reduction in platelets, and in other cases the reverse may be true. It has been suggested that an antigenic relationship exists between platelets and vascular endothelium with a common etiology for both.[260]

---

*No. SC-87; General Electric Silicones, Waterford, N. Y.

Another defect in the clotting mechanism associated with prolonged bleeding time is hypoprothrombinemia. The experience of surgeons prior to the discovery of the value of vitamin K therapy amply attests to the capillary bleeding in patients with obstructive jaundice.

A surprising relationship between a severe abnormality in the coagulation mechanism and a normal bleeding time test exists in hemophilia. With the minor wound inflicted in the test, the capillaries are sufficiently resilient to shut off immediate bleeding. However, it is not at all uncommon for bleeding to return at the puncture site an hour or more later. Occasionally such recurrent bleeding may be sufficiently severe to cause concern. If hemophilia is strongly suspected, laceration of the skin should be zealously avoided, and punctures for tests should be limited only to those necessary for diagnosis and treatment. The bleeding time is an unnecessary test in this condition. In other diseases simulating hemophilia, such as deficiency of the 2 plasma thromboplastin factors, plasma thromboplastin component (PTC) and plasma thromboplastin antecedent (PTA), Rosenthal[261] reported usually normal bleeding times.

There exists a nondescript group of hemorrhagic diatheses, most of which have appeared in the older literature, associated with a prolonged bleeding time. Among these might be mentioned the hereditary capillary fragility group, variously labeled pseudohemophilia A, von Willebrand's disease, and purpura of capillary weakness. Glanzmann's thrombasthenia is another type in which some unknown defect of platelets, which are normal in numbers, is reputedly responsible for abnormal bleeding. It is probably the same disease that von Willebrand described. Pseudohemophilia B also falls into this group of diseases with prolonged bleeding time. As our knowledge of the clotting mechanism is elaborated, this group becomes more circumscribed.

Bleeding time may be prolonged in elderly individuals in whom no defect in clotting mechanism exists. Such abnormal bleeding is purportedly related to lack of elasticity of capillaries in the aged, though bleeding time does not measure capillary fragility (hyperpermeability) but rather response of capillaries to injury.

Another parodoxical relationship exists in which purpura (nonthrombocytopenic) is pronounced, capillary fragility tests are markedly abnormal, and yet the bleeding time tests are usually normal. Some of the allergic purpuras (Schönlein-Henoch) fit into this category as do those related to sepsis, uremia, and vitamin deficiencies.

CAPILLARY FRAGILITY TESTS

Capillary fragility tests can be roughly divided into 2 principal groups—those applying pressure and those applying suction. Many modifications, aimed chiefly at standardization of the technic, have been devised.

Method of Rumpel-Leede[262] (tourniquet test)

This test, which originally consisted in placing a tourniquet about the arm and observing the number of petechiae in the area distal to it, has had so many modifications of time of application and levels of pressure that authorship of most of the modifications can hardly be traced. In general, the tourniquet has been replaced by a blood pressure cuff. There is no agreement as to whether the blood pressure should be midway between diastolic and systolic pressures or whether 100 mm. Hg is the desirable level. The time of application is variably suggested as 5-10 min. There is some difference as to whether the entire extremity should be examined for petechiae or whether the number in a limited area should be counted.

There is also no unanimity of opinion concerning normal values. In general, it can be said that most **normal individuals** show relatively few petechiae, perhaps 10 or less. Those with a marked capillary fragility show many petechiae, sometimes almost covering the entire skin. We should like to add a few comments based on our experience with these modifications.

It is not at all uncommon for a band of petechiae to appear at the lower edge of a tourniquet or blood pressure cuff where the skin has been pinched. We suggest, therefore, that this area be disregarded in an appraisal of the results. Another observation is that it is not at all uncommon for petechiae to appear several minutes after the application of pressure or suction. For this reason, our routine procedure in any capillary fragility test is to include a re-examination of the area at least 30 min. after the application of pressure or suction.

Method of Quick[263]

1. Apply blood pressure cuff to the upper arm and inflate to a pressure midway between systolic and diastolic levels.
2. Maintain pressure for 5 min.
3. Release cuff and inspect arm, wrist, and hand for petechiae.

Normal: Up to 5 petechiae.*

Method of Gothlin[264]

1. Carefully inspect the forearms for petechiae or other marks which might be mistaken for them.
2. Mark off in ink an area 6 cm. in diameter in the antecubital fossae on each upper extremity.
3. Apply blood pressure cuffs to both arms and inflate simultaneously to 35 mm. Hg, maintaining this pressure for 15 min. with the subject resting the forearms on a table.
4. Release the pressure and inspect the outlined area for petechiae, using a magnifier and bright light.
5. Multiply the number of petechiae in both arms by 2.

If the **Gothlin index** is 8 or less, the result is considered normal; if more than 12, capillary fragility is considered abnormal. If the value falls between 8 and 12, the results are equivocal, and the following step is suggested.

6. Not before 1 hr. and preferably the next day or later, repeat the procedure, with the pressure at 50 mm. Hg for 15 min. Note the number of petechiae. Do not double this number, as in step 5, but add it to the results of step 5.

If the sum of steps 5 and 6 exceed 12, the result is considered abnormal.

Normal: 0 to 12 petechiae (**Gothlin index**).

Petechiometer method†

The apparatus consists of a plastic suction cup† 2 cm. in diameter, with a built-in spring-activated suction piston. A simple locking device enables adjustments of negative pressures at 10, 20, and 30 cm. of negative pressure. A built-in magnifying lens enables visualization of the area subjected to the test. The kit also contains a plastic circular disk the size of the suction cup, with the central area marked off by a circle 1 cm. in diameter.

1. Inspect a nonhairy skin area in either the subclavicular fossa or the inner aspect of the arm for blemishes which might be mistaken for petechiae. Note and eliminate from the counts.
2. Rim the suction cup with lubricant to establish an airtight seal and then apply it to the skin at 20 cm. negative pressure for 1 min.
3. Release the pressure and place the circular disk on the skin area.

Observe only the central 1 cm. area for petechiae. If less than 4 petechiae appear, the **capillary resistance is normal.** If 4-8 petechiae are present, the test is equivocal and is repeated with 30 cm. negative pressure at another site. More than 8 petechiae should appear at this level of pressure for the test to be considered positive. If more than 8 petechiae appear at −20 cm. pressure in the original test, repetition at −10 cm. at another site simply elaborates on how fragile the capillaries are.

Comments on capillary fragility

Capillary fragility (or capillary resistance) is a reflection of the state of the vascular bed, one of the lines of defense in hemostasis. The vascular tree may be affected by a wide variety of factors which may or may not be related to the clotting mechanism. As a result, abnormalities in capillary fragility must be interpreted as nonspecific phenomena indicating the need for further investigation of the patient.

In the group of capillary purpuras with normal platelet counts, the capillary fragility is variable but at times may be markedly abnormal. We have seen mechanical purpura resulting from application of a tourniquet or blood pressure cuff or associated with wearing of tight garters in patients in whom the capillary fragility test has been generally normal. Griffin[265] has emphasized the abnormal Gothlin indices in a large percentage of patients with diabetes and hypertension. He claims reversal of the abnormality by administration of rutin or other flavanoids. Variable values are likewise noted in sepsis, allergy, drug intoxications, scurvy, uremia, and senility. Ackroyd[260] maintains that in allergy the basic lesion causing purpura is an increased capillary fragility. Other conditions which may be associated with increased capillary fragility without coexisting abnormality of clotting mechanism include hereditary capillary fragility, hereditary capillary telangiectasia, Glanzmann's thrombasthenia, Kaposi's sarcoma, rheumatic heart disease, and leukemia. Abnormal capillary resistance to negative pressure has also been seen in patients with acute myocardial infarction.

Thrombocytopenia is almost universally associated with an increased capillary fragility. This relationship obtains whether the thrombopenia is primary or is secondary to disease, drug intoxication, etc. In such instances the capillary fragility parallels the level of the platelet count and the skin bleeding time. Exceptions to such parallelism are occasionally found. As a rule, the capillary fragility test reflects the severity of the disease and usually returns to normal in patients whose disease improves with treatment, whether the therapy be splenectomy or the removal of secondary factors. Occasionally the capillary fragility may remain abnormal in patients who appear clinically cured by splenectomy.

---

*From Quick, A. J.: Hemorrhagic diseases, Philadelphia, 1957, Lea & Febiger.

†Rexall Drug Co., Los Angeles, Calif.

In occasional cases of polycythemia vera, even with a high platelet count, increased capillary fragility is seen, which is also noted in nonthrombocytopenic purpura.

In contrast with thrombocytopenia there are very gross abnormalities of the clotting mechanism which are generally associated with normal capillary fragility. These include hemophilia and hemophilia-like diseases (AHG, PTC, and PTA deficiencies) and fibrinogenopenia.

Hypoprothrombinemia due to any cause may be associated with abnormalities of capillary fragility if the prothrombin level sinks low enough. When the prothrombin status is returned to normal by therapy with vitamin K, the capillary fragility follows the same course.

BLOOD PLATELET COUNTING

There are several technics available for counting blood platelets. In the **indirect** counting method platelets are counted in their relationship to red blood cells on fixed films. This method is least reliable since the results depend on the distribution of platelets and on the red blood cell count. The permanent record is an advantage because it allows study of platelet morphology and gives an impression of the number of platelets.

The **direct** counting method is the most accurate method at the present time. There are 3 methods: (1) Rees-Ecker method, (2) phase microscopy, and (3) Coulter counter (p. 1108).

Indirect counting methods

Method of Dameshek[266]

Reagent:

1. Dissolve 0.15 gm. brilliant cresyl blue in 100 ml. distilled water containing 8 gm. sucrose and 0.4 gm. sodium citrate.
2. Mix well and filter.
3. Add 3 drops 1:10 dilution of formalin (40%) as a preservative.

Procedure:

1. Discard the first drop of blood obtained by puncturing the skin.
2. Place a fairly large drop diluting fluid over the puncture wound and gently press the finger so that a small amount of blood wells up into the drop of staining solution.
3. The proportion of blood to stain should be about 1:5.
4. Transfer the mixture of blood and stain to a cover glass; then invert the cover glass and drop it on a slide.
5. Wait 15-45 min.
6. Examine with an oil immersion objective.
7. Count as directed below.

Reticulocytes can be counted in the same preparation.

Counting blood platelets

Count all the erythrocytes and blood platelets in consecutive fields until 250 erythrocytes have been counted. Count 4 such fields after the 4-field meander method.

Calculate the number of blood platelets in 1 c.mm. blood by the following formula:

$$\frac{\text{Patient's red count}}{1000} \times \text{No. blood platelets counted}$$

$= $ No. blood platelets in 1 c.mm. blood.

Example:

1000 red blood cells counted.
65 blood platelets counted.
Patient's erythrocyte count 5,000,000.

$$\frac{5{,}000{,}000}{1000} \times 65 = 325{,}000 \text{ blood platelets in 1}$$

c.mm. blood.

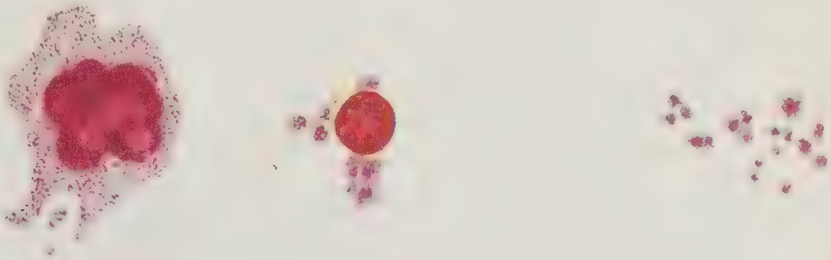

Fig. 399. Development of blood platelets from a megakaryocyte. (Wright stain.)

The **normal** platelet count with the Dameshek method is 500,000-900,000; average 716,000/c.mm.

Direct counting method

Rees-Ecker method

Rees-Ecker diluting fluid[267]:

Sodium citrate	3.8 gm.
Neutral formaldehyde, 40% .	0.2 ml.
Brilliant cresyl blue . . .	0.1 gm.
Distilled water	100 ml.

Filter and centrifuge before use. Keep stoppered in a refrigerator.

Procedure:

1. Draw blood, capillary or venous (aspirated into siliconized syringe and test tube), into a red cell pipet to the 0.5 mark.
2. Draw centrifuged and filtered diluting fluid to the 101 mark.
3. Shake in a pipet rotor for 5-10 min.
4. Expel 4 drops and fill a standard counting chamber, both sides.
5. Allow to stand for 15 min. in a closed Petri dish kept moist with wet filter paper in the top half.
6. Count the platelets in the finely ruled center area of each chamber.

Platelets are bluish and must be distinguished from debris.

Calculation: The counted space measures 1 × 1 × 0.1 c.mm. Since 2 such spaces are counted, the platelets in a space of 0.2 c.mm. are enumerated. To obtain the number of platelets in 1 c.mm., multiply the total count of the 2 chambers by 5 × 200 (dilution factor).

Phase microscopy method of Brecher-Cronkite[268]

Diluting fluid: 1% ammonium oxalate in distilled water is used. Store in a refrigerator and filter before use.

Procedure:

1. Use capillary blood or venous blood obtained by the 2-syringe method; the second syringe should be siliconized.
2. Empty blood into a siliconized test tube.
3. Draw blood to the 0.5 mark in 2 red cell pipets and dilute with diluting fluid to the 101 mark.
4. Shake pipets for 3 min.
5. Expel the first 4 drops and fill both chambers of a hemacytometer. Use No. 1 cover slip.
6. Place the hemacytometer in a closed Petri dish kept humid with moist filter paper in the top half.
7. Count the platelets by phase microscopy in the central sq.mm. of each chamber.

Calculation: This is the same as for the Rees-Ecker method.

The direct counting method should always be supplemented by a blood film to confirm the number counted and to study platelet morphology.

Interpretation: The diagnosis of thrombocytopenia and of thrombocythemia is essentially based on the platelet count. Platelet morphology will help establish the diagnosis of thrombopathia. The platelet count often reflects bone marrow activity. If the bone marrow is depressed, hypoactive, or aplastic, the platelet count will fall. If the bone marrow recovers, the platelet count will improve although it may lag behind several weeks. In certain myeloproliferative syndromes, though the bone marrow may be severely damaged, the platelet count may actually be increased.

CLOT RETRACTION

There are many modifications of the clot retraction test, which at best is only a rough screening test of the clotting mechanism.

1. Obtain 2-3 ml. blood by venipuncture and transfer to a clean test tube, preferably a Wassermann tube.
2. Stopper and leave in a 37° C. water bath.
3. Inspect hourly for beginning clot retraction and then every 2 or 3 hr. for completion of retraction.
4. Observe the quality of the clot and possible lytic activity.

Normal clot retraction: This begins in 1 hr., and a definite margin of serum is seen between the clot and the test tube walls in 2 hr. At the end of 24 hr. the clot contracts fully, leaving an area of clear serum above it and surrounding its sides.

Comments: Strict standardization of this method is necessary since the result will depend on (1) the volume of blood in the test tube, (2) the diameter of the test tube, (3) the temperature of the water bath, (4) the type of glassware, (5) the method of blood collection, (6) the handling of the test tubes, (7) the fibrinogen content of the blood, and (8) the state of the platelets and the plasma coagulation factors present (see discussion that follows).

The test can be rendered more sensitive by siliconizing the test tubes so that the normal range will extend up to 30 min.

Clot retraction depends mainly upon 2 factors: blood platelets and plasma coagulation factors. It was thought at one time that clot retraction depended wholly on the number of platelets. Usually the platelet count is below 100,000/c.mm. in most specimens of blood which do not retract, but occasionally poor retraction is seen when the platelet count is normal, such as in thrombasthenia. In advanced liver diseases with hypoprothrombinemia, clot retraction may be poor. In hemophilia the coagulation time is markedly delayed, but once a clot has formed, it retracts normally. There is some evidence that clot retraction can be correlated to venous thrombosis.

TESTS FOR ABNORMALITIES OF CLOTTING MECHANISM

Determination of clotting time

Capillary tube method

Materials:

1. 3-4 in. capillary tubes.
2. Capillary blood specimen.

Procedure:

1. Obtain a drop of blood by skin puncture and allow to enter several capillary test tubes.
2. Break off small pieces of the tubes at 30 sec. intervals until a fine thread of fibrin persists at the site of separation of fragments of the capillary tube.

The time from skin puncture to the formation of the fibrin thread is the clotting time, measured by a stopwatch.

Normal: 2 to 4 min.

This method is applicable only in infants (venipuncture difficult) and in patients receiving heparin therapy. The unavoidable release of tissue thromboplastin makes this method only a very rough measure of coagulability.

Modified Lee-White method

Materials:

1. 3 clean test tubes.
2. 2 clean syringes, 1 coated with silicone.
3. Water bath.
4. Stopwatch.

Procedure:

1. Draw blood from a vein by a clean puncture, avoiding an undue amount of suction, by the 2-syringe method.
2. Remove the needle from the syringe and gently transfer 1 ml. quantities of the blood specimen to each of the 3 test tubes, prewarmed in a 37° C. water bath.
3. After approximately 5 min., gently tilt the test tube which was filled last (as it contains the potentially contaminated blood drawn first) and observe for clotting. If a clot has not formed, tilt this same tube every 30 sec. until the blood is no longer liquid.
4. At about 1 min. later, check the second tube for clot formation as described for tube 1. Tilt this second tube every 30 sec. until a firm clot is detected and then check the third tube, which is the tube which was filled first (containing the blood least contaminated with thromboplastin).
5. Finally tilt tube 3 until a clot has formed.

The coagulation time is the length of time required for the blood to clot in tube 3.

Normal: 8-14 min.

Clot timers

Two automatic timing devices of clotting are available.

The Clot-Timer* operates on the principle that clotting produces a change in the viscosity and in the surface tension of the clot or plasma. As soon as clotting begins, electrodes automatically stop a counting device.

The Thromboblastograph* makes visual and photokymographic observations simultaneously on 3 different samples of blood.

Thromboblastography is based on the fact that a plunger is inserted into a rotating cap which contains the blood. Attached to the plunger is a mirror which reflects a light beam onto a scale and onto photographic film. As long as the blood is liquid, the plunger will remain stationary even though the cap rotates. As soon as the blood begins to clot, it will carry the plunger with it, and the reflected beam will parallel the mirror movement. This method is useful if a graphic record of hypercoagulability or hypocoagulability of the blood is desired and if fibrinolytic activity or thromboplastin generation are studied.

Plasma recalcification method—Quick[269]

Materials:

1. M/10 Sodium oxalate.
   Prepare by dissolving 1.34 gm. sodium oxalate in 100 ml. distilled water (total).
2. M/100 Calcium chloride.
   Prepare by dissolving 0.11 gm. anhydrous calcium chloride and 0.42 gm. sodium chloride in 100 ml. distilled water.
3. Centrifuge, stopwatch, and venous blood.

Procedure:

1. Draw 4.5 ml. blood by 2-syringe method; remove needle from syringe, and immediately transfer blood to 0.5 ml. oxalate solution.
2. Mix thoroughly by inverting stoppered tube several times.
3. Divide the mixture into 2 approximately equal portions.
4. Centrifuge 1 portion at 1000 r.p.m. for 5 min. (platelet-rich plasma) and the other at 3000 r.p.m. for 5 min. (platelet-poor plasma).
5. Withdraw 0.1 ml. plasma from each specimen and place in separate test tubes in a water bath at 37° C.
6. Add 0.2 ml. M/100 calcium chloride to each sample of plasma and begin timing immediately with a stopwatch.
7. Keep the tubes in a water bath and tilt occasionally until a clot forms. This is the end point of the test. Note the exact time of clot formation.

Normal:

Slow centrifugation: 95-135 sec.

Fast centrifugation: Not more than 15 sec. longer than in slow centrifugation.

Comments: The plasma recalcification time is the time required for a fibrin clot to appear in decalcified plasma. The blood specimen is first prevented from clotting by removing calcium with a known amount of sodium oxalate. Calcium is then added in the form of a known quantity of calcium chloride to start the clotting mechanism.

---

*Mechrolaboratories, Inc., Mountain View, Calif.

*Scientific Products Division, American Hospital Supply Corp., Evanston, Ill.

The recalcified plasma clotting time is prolonged in marked hypoprothrombinemia. In deficiencies of antihemophilic globulin (AHG), plasma thromboplastin component (PTC), and plasma thromboplastin antecedent (PTA), the clotting time of recalcified plasma is also prolonged. The degree of prolongation appears to be related to the degree of deficiency. A prominent feature of these deficiencies is that the clotting time of the platelet-poor (rapidly centrifuged) plasma shows a greater prolongation of clotting time than that of the platelet-rich plasma (slow centrifugation).

As a test of the adequacy of plasma thromboplastin, it has been supplanted by the prothrombin consumption test.

Heparin-retarded blood coagulation time of de Takats[270, 271]

Principle: The plasma recalcification time (i.e., the spontaneous clotting of blood) is determined after known quantities of heparin are added to delay the process and increase its sensitivity so that hypercoagulability and hypocoagulability of the blood can be better appreciated.

Materials:

1. Heparin solution.
   Use heparin solution containing 0.004 mg. heparin/0.1 ml. saline, which is made by diluting standard 10 mg./ml. heparin solution 1:250 with isotonic saline.
2. Venous blood freshly drawn, using 2-syringe method.

Procedure:

1. Place 0.1 ml. heparin solution in a clean dry glass test tube in a water bath at 37° C.
2. Add 1 ml. blood to this tube and invert twice.
3. At the end of 12 min., tilt the tube gently at 1 min. intervals until a firm clot has formed. The end point occurs when the tube can be completely inverted without any fluid breaking away from the clot.

Normal: 20-35 min.; average, 27.5 min.

Several modifications of this test have been described. Soulier[272] uses 4 test tubes each containing 0.5 ml. oxalated plasma centrifuged 5 min. at 2000 r.p.m. to which is added M/40 calcium chloride solution which contains increasing quantities of heparin. Heparin concentrations are as follows:

No heparin
0.3 unit/ml.
0.7 unit/ml.
1 unit/ml.

This test can be performed on platelet-rich and platelet-poor plasma to test the antiheparin activity of platelets.

Rosenthal states that the "heparin clotting time appears to be the most valuable single test or index of coagulation." He emphasizes that the test may be used in conditions associated with rapid clotting processes as well as with those having prolongation of coagulation. Prolonged heparin clotting times were found in the deficiency states involving AHG, PTC, and PTA. In these conditions the heparin clotting test was found more sensitive than standard procedures such as the Lee-White technic. In addition to these classic conditions, Rosenthal found that 50% of patients with chronic myelocytic or lymphocytic leukemia had prolongation of the heparin clotting time. This previously unreported coagulation defect was closely related to the degree of hemorrhagic diathesis in these patients even though they did not have thrombocytopenia of a degree usually considered critical.

The heparin clotting time was found prolonged in some patients with bone marrow depression and slight thrombocytopenia, such as may occur in malignant lymphomata and other diseases related to the hematopoietic system. Although these patients showed no clinical manifestations of hemorrhage, they had prolongation of the heparin clotting time.

Rosenthal[273, 274] found evidence of accelerated coagulability in 74% of patients within 3 weeks following the onset of myocardial infarction. The heparin clotting time was shortened in these patients with a mean of 18.7 min., ranging from 11-20 min. Routine clotting times and platelet counts were normal. A control group of patients with cardiovascular disease but without myocardial infarction showed normal values. Dicumarol was found to have marked effect in prolonging the heparin clotting time.

Comments on clotting time determinations

Measurement of the clotting time may or may not disclose the presence of an abnormality in the clotting mechanism. Finding a prolonged clotting time should always initiate further investigation of disturbances in coagulation. Since prolongation of the clotting time may be due to deficiencies of plasma factors, such as AHG, PTC, PTA, fibrinogen, accelerator factors, and prothrombin, special procedures directed at determining these specific defects must be pursued. Anticoagulants, either acquired or idiopathic, may have to be considered. A screening procedure for determining whether there is a deficiency or an anticoagulant has been described by several authors,[261, 275-280] using technics of matching mixtures of blood.

Differentiation of plasma defects and circulating anticoagulants

Principle: When an abnormal clotting time has been found, the question arises as to whether it is due to a plasma defect or to a circulating anticoagulant. Differentiation of these two mechanisms can be made by determining the coagulation time of mixtures of normal and abnormal blood.

Materials: The same materials as in the plasma recalcification method of Quick (p. 1199) are used.

Procedure (adapted to method of Cartwright[281]):

1. Add 4.5 ml. venous blood from the patient to 0.5 ml. M/10 sodium oxalate.
2. Repeat this procedure in another tube, using blood of a normal subject.
3. Mix each sample thoroughly.
4. Centrifuge both specimens of oxalated blood in the same centrifuge at 1000 r.p.m. for 5 min.
5. Prepare a series of mixtures of the 2 plasmas as follows:

	Tube					
	1	*2*	*3*	*4*	*5*	*6*
Patient plasma (ml.)	0.2	0.4	0.1	0.1	0.1	0.0
Normal plasma (ml.)	0.0	0.1	0.1	0.2	0.4	0.2

6. Mix the contents of each tube thoroughly.
7. Transfer 0.1 ml. samples of each tube to 6 clean test tubes and place in a water bath at 37° C.
8. Add 0.2 ml. M/100 calcium chloride to each tube, mix, and begin timing immediately with a stopwatch.
9. Observe each tube for firm clot formation and record time.

Tube 6 is the **normal control** and should have a clotting time of 95-135 sec.

Tube 1 should have a clotting time prolonged beyond 135 sec.

If the patient's condition is due to a deficiency in some plasma factor necessary for coagulation, the addition of oxalated normal plasma will correct the deficiency, and under such conditions tubes 2-5 will have normal coagulation times.

If the disorder in the patient is due to a circulating anticoagulant, tubes 2-5 will show increased coagulation times, with progressively diminishing values from tubes 2-5.

After it is ascertained whether the coagulation defect is due to deficiency of plasma factors or to circulating anticoagulant, special tests must be carried out to ascertain the specific elements involved. These include the following procedures:

A. Tests for plasma deficiencies
  1. Partial thromboplastin time (PTT)[282]
  2. Assay of antihemophilic factor[282]
  3. Prothrombin time
  4. Prothrombin consumption time (plasma or serum)
  5. Studies of mixtures
  6. Fibrinogen determination
  7. Thromboplastinogen activity test[283]
  8. Thromboplastin generation test[284]

B. Tests for anticoagulants
  1. Antithrombin and antithromboplastin[285]
  2. Hyperheparinemia[286]

TESTS FOR PLASMA DEFICIENCIES

Prothrombin time determinations

Prothrombin time is the clotting time obtained when an excess of thromboplastin and calcium is added to oxalated plasma under standardized conditions.

Plasma prothrombin time—Quick[287] one-stage prothrombin time

Reagents:

1. M/10 Sodium oxalate.
   (a) Dissolve 1.34 gm. sodium oxalate in enough distilled water to make 100 ml.
2. M/40 Calcium chloride.
   (a) Dissolve 0.28 gm. anhydrous calcium chloride in enough distilled water to make 100 ml.
3. Thromboplastin solution.

Use commercially available rabbit or human brain thromboplastin preparation (Simplastin*) to which calcium chloride and sodium chloride have already been added.

Prepare thromboplastin solution exactly according to the manufacturer's instructions.

Procedure:

1. Into a conical graduated centrifuge tube measure 0.5 ml. M/10 sodium oxalate.
2. Withdraw venous blood with special precautions to avoid trauma and add exactly 4.5 ml. to the oxalate and mix quickly to prevent clotting.
3. Centrifuge at 1500 r.p.m. for 5 min.
4. Withdraw plasma with a dropper and place in a test tube; then transfer the tube to a 37° C. water bath.
5. Pipet 0.2 ml. reconstituted Simplastin into at least 4 test tubes and then place them in the 37° C. water bath for at least 3 min.
6. With a 0.1 ml. micropipette transfer 0.1 ml. whole plasma previously warmed to 37° C. to the tube containing the warmed 0.2 ml. Simplastin.

---

*Warner-Chilcott Laboratories, Morris Plains, N. J.

7. Blow the plasma out of the pipet quickly and start the timer simultaneously.
8. Keep the tube warmed and tilt about twice per sec.
9. When the first evidence of clotting appears, stop the stopwatch and record the time.
10. Repeat the test with a normal control, e.g., Protrol.*

Report prothrombin time in sec. or as **% normal activity,** always recording the control results as well.

If the venous blood to be tested is kept at room temperature, the prothrombin time should be determined within 1 hr. after collection. If the venous blood is kept at 4° C., the prothrombin time should be determined within 4 hr.

With an active preparation of thromboplastin, **normal human plasma** will clot consistently in 12-14 sec.

Comments on Quick one-stage prothrombin time

Since Quick's original publication, numerous modifications of the method have been devised in order to simplify the procedure for routine clinical laboratory use, improve on the reagents, or correct certain objections to the basic principles in the test.

The activity of a given batch of thromboplastin should be checked against normal controls. To circumvent the possibility that the so-called normals are not truly normal, commercial preparations of lyophilized plasma are available as controls.[288]† The prothrombin time of an unknown sample is greatly dependent on the thromboplastin potency and should be reported in seconds, with an accompanying note of the time for the normal control.

Curves are constructed with varying dilutions of plasma, with time (sec.) as one component and percentages as another. Such calibration curves are used as references for reporting tests in percentages. An objection to the method as originally reported by Quick is that in the higher percentage ranges the slope of the curve is so steep that small increments of time reflect large changes in percentages. To circumvent this objection, various dilutions of the test plasma have been suggested. Usually the dilution is in the range of 1:10 but may be adjusted at other levels for special situations. Although saline solution has been recommended as the diluent by some, it is now generally agreed that it should not be used because it dilutes all coagulation factors in plasma. Prothrombin-free plasma is one of the diluents most universaly recommended. There is some question as to whether this should be human or animal plasma. The adsorbents used for preparation of such prothrombin-free plasma have been barium sulfate or passage through filter paper pads containing high concentrations of asbestos.

A method that considers many of these factors is the one by Rosenfield and Tuft[289] as modified by Alexander and deVries[290] and is recommended.

Prothrombin time—Rosenfield-Tuft,[289] modified by Alexander-deVries[290]

Reagents:

1. M/10 Sodium oxalate.
   (a) Dissolve 1.34 gm. anhydrous sodium oxalate in 100 ml. distilled water.
2. M/10 Potassium oxalate.
   (a) Dissolve 8.423 gm. crystalline potassium oxalate in distilled water and dilute to 1000 ml. with distilled water.
   (b) Use 1 ml. this solution as anticoagulant for 9 ml. blood, which is used for the preparation of prothrombin-free plasma.
3. M/40 Calcium chloride.
   (a) Dissolve 2.77 gm. purified anhydrous calcium chloride in distilled water and dilute to 1000 ml. with distilled water.
4. Thromboplastin: See Quick method and comments (p. 1201).
5. Prothrombin-free human plasma:
   (a) Collect 9 ml. blood from each of at least 5 normal subjects and place each in 1 ml. M/10 potassium oxalate and mix.
   (b) Separate the plasma and pool.
   (c) Divide the plasma pool into 2 portions, using one for adsorption with barium sulfate and the other for diluting the normal or test plasma.
   (d) Add 100 mg. barium sulfate powder for each ml. plasma, shake thoroughly, and incubate for 10 min. at 37° C.
   (e) Centrifuge at 3000 r.p.m. for 30 min. and pour off the supernatant fluid.

Refrigerate this at 4° C. until ready for use. Since this material must be used within 2 hr. after its preparation, Frommeyer[291] recommends lyophilization in order to maintain its potency.

Lyophilized prothrombin-free plasma is reconstituted with buffer at the time of its use.

Preparation of curve for time/percentage relationships: Dilute **fresh, pooled, normal** plasma serially (10, 12½, 20, and 30%) with the prothrombin-free plasma prepared as just described. On each dilution perform a Quick prothrombin time test (p. 1201) and plot a curve with the time in seconds against the concentration in per cent (Fig. 400).

Procedure:

1. Place 0.5 ml. M/10 sodium citrate in a test tube.
2. Add 4.5 ml. venous blood and mix.

---

*Knickerbocker Laboratories, New York, N. Y.

†Diagnostic Plasma, Warner-Chilcott Laboratories, Morris Plains, N. J.

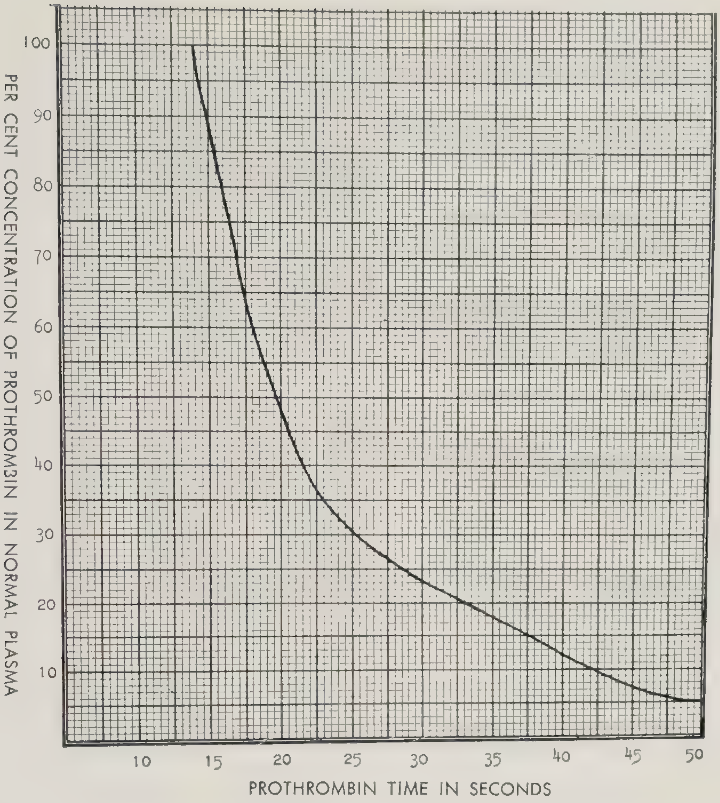

Fig. 400. Curve constructed for Quick prothrombin time determination. Such calibration curves are used as references in reporting prothrombin time in percentage.

3. Centrifuge at 1000 r.p.m. for 5 min.
4. Remove the supernatant plasma with a clean pipet and transfer it to a clean test tube.
5. Place all the reagents and tubes used hereafter in a water bath at 37° C.
6. Place 0.1 ml. plasma and thromboplastin solution in a clean Kahn tube and shake gently to ensure mixing.
7. With stopwatch in hand, blow in 0.1 ml. of M/40 calcium chloride solution, and begin timing.
8. Remove the tube from the water bath periodically and observe the time required for a clot to form; check the concentration in percentage on the curve prepared as shown in Fig. 400.

Comments: The first steps in prothrombin time determination with this test are essentially the Quick technic, with a time-concentration curve prepared by dilution with prothrombin-free plasma. If the result of this determination falls in the flat part of the time-concentration curve, 25 sec. or longer, the result may be recorded as a final figure. However if a shorter time is consumed, it is recommended that the unknown plasma sample be diluted 1:10 with the prothrombin-free plasma, **not saline solution,** and the prothrombin time on a 0.1 ml. aliquot of this be determined as in the method for undiluted plasma. The result in per cent concentration is then multiplied by 10.

Clot-timer technic

Reference has been made to automatic clot-timers,* which are well suited for the determination of the 1-stage prothrombin time. The plasma is placed in a flat metal cuvet which is kept at 37° C. A rotor rotates through the mixture of thromboplastin, calcium chloride, and plasma and stops as soon as a fibrin band produces contact between it and a nonmovable rod.

Discussion of one-stage prothrombin time method

The speed of the formation of the clot depends on 4 clotting factors: prothrombin, factor V, factor VII, and Stuart-Prower factor, assuming that fibrinogen and circulating anticoagulant activity are normal. Because of the fact that this test embraces 4 factors, it is thus possible that a reduction of prothrombin activity of 40-50% of normal, as may occur in acute hepatitis, may be completely masked by factor V and factor VII activity. Similarly, a reduction of factor VII up to 30% will not affect the 1-stage prothrombin time, whereas a mild degree of reduction of both prothrombin and factor VII will by synergistic action prolong the prothrombin time. The concentration of factor V appears to be critical and is not influenced by vitamin K_1 (production of prothrombin and of factor VII is dependent on vitamin K_1). Factor VII is of importance only if reduced.

---

*Mechrolaboratories, Mountain View, Calif.

It has long been known that clotting defects accompany liver disease.[293] These defects vary according to the underlying liver disease. In acute viral hepatitis, PTA, Stuart-Prower, and PTC are most markedly reduced; next follow factor VII and prothrombin; least affected is factor V. In a few cases, factor V, factor VII, and prothrombin are actually increased.

In chronic hepatitis and cirrhosis the factors may be within normal limits, but factor VII is frequently decreased, and then may follow factor V and prothrombin as well as the antithrombins.

The 1-stage method is the most common method for controlling anticoagulant therapy with coumarin and related drugs. These drugs reduce both prothrombin and factor VII activity. Initially, within the first 24 hr., factor VII is more rapidly depressed and within a few days there follow prothrombin and Stuart-Prower factor. After administration of vitamin K_1, factor VII recovers more rapidly than does prothrombin. From the preceding discussion it is clear that a prolonged prothrombin time may be due to variations in 3-4 factors or to changes in only 1 or 2 of them.

Since vitamin K_1 administration will correct prothrombin and factor VII deficiencies, provided that liver function is adequate, but will not correct factor V deficiency, which is also not corrected by transfusion of stored blood, it is at times advisable to utilize correction studies to determine which factor is involved in the prolongation of the prothrombin time. These correction studies are not quantitative studies, but they allow separation of factor V, factor VII, and prothrombin deficiencies.

Correction studies of one-stage prothrombin time

Prepare the following mixtures and perform 1-stage prothrombin time tests as follows:

0.9 ml. patient's plasma + 0.1 ml. stored serum (supplies factor VII).

0.9 ml. patient's plasma + 0.1 ml. fresh $BaSO_4$ plasma (supplies factor V).

0.9 ml. patient's plasma + 0.1 ml. stored oxalate plasma (supplies prothrombin).

Whichever of the added factors corrects the originally prolonged prothrombin time can be considered the factor primarily responsible for the prolongation.

Table 241. *Main coagulation factors in various blood fractions used in correction studies**

	Normal plasma	*Normal serum*	*Aluminum hydroxide, $Al(OH)_3$, barium sulfate, $BaSO_4$, adsorbed plasma*
Fibrinogen	+	−	−
Prothrombin	+	−	+
Factors V and VI	+	−	−
Factor VII	+	+	+
Factor VIII	+	−	−
Factor IX	+	+	+
Factor X	+	+	−

*From Bauer, J. D., Toro, G., and Ackermann, F. G.: Bray's clinical laboratory methods, St. Louis, 1962, The C. V. Mosby Co.

Microprothrombin method

Miale[292] described a micromethod for prothrombin determination of oxalated blood which is based on the 1-stage prothrombin method of Quick and is useful if patients resent frequent venipunctures.

One-stage prothrombin method—bedside technic (Manchester technic)

This procedure is indicated if venipuncture is impossible, but it cannot be correlated with the Quick 1-stage method.

One drop of blood from a skin puncture is placed on a glass slide and mixed with one drop of thromboplastin. The periphery of the mixed drop is touched at intervals of 2-3 sec. with a glass rod until fibrin formation is noted. Illumination by transmitted light aids the visualization of the fibrin threads. A normal control should be run with each test. It will clot in 15-25 sec.

Two-stage method of prothrombin time—Warner, Brinkhous, and Smith[294-296]

The basic principle of this method is the measurement of thrombin yield against a standardized solution of fibrinogen. Just as with other prothrombin time methods, the 2-stage technic has undergone numerous modifications. Its complexity has been a bar to routine technical use, but it has served as a useful investigative tool.

The prothrombin methods to be described are the result of an increasing awareness that the Quick 1-stage prothrombin time has certain defects. Thus it may happen that a patient whose prothrombin time is within the therapeutic range may hemorrhage. On the other hand, patients who are apparently well controlled on anticoagulant therapy may develop thrombotic episodes. The previously mentioned dilution of the plasma represents an attempt to increase the sensitivity of the 1-stage method. It is also believed that changes in fibrinogen and factor V concentration might influence the prothrombin time. The P and P method of Owren and Aas was originally introduced to reflect changes of prothrombin and proconvertin (factor VII) only; hence the name P and P.

P and P method of Owren and Aas[297]

The theoretical basis of the test is as follows. The amount of thrombin formed by the interaction of prothrombin and thromboplastin is a measurement of the concentration of prothrombin, as it is assumed that 1 unit of thrombin will be produced by 1 unit of prothrombin. Thus the amount of thrombin produced can be taken as a measure of the amount of prothrombin present in the plasma. In this method, plasma is defibrinated and then diluted with oxalated saline solution. This diluted plasma is then added to a mixture of thromboplastin, calcium, and buffer. The thrombin generated is measured by adding a fixed amount of this mixture to a standard solution of fibrinogen.

The disadvantages of this method lie in the action of plasma antithrombins and the fact that concentration of factor V and factor VII prevents a stoichiometrical conversion of prothrombin to thrombin.

Reagents:

1. Thromboplastin derived from human brain.
   - (a) Free human brain from pia and blood vessels.
   - (b) Wash and grind the gray substance in a mortar with 0.9% sodium chloride solution to a fine emulsion. Emulsification is facilitated by applying a mechanical blender.
   - (c) Dilute the emulsion with 0.9% saline to which 20% Veronal buffer is added. Approximately 5 ml. solution should be used for each gm. brain substance.
   - (d) Allow the extract to stand for about 2 hr. at 45° C.
   - (e) Strongly centrifuge for 15 min.
   - (f) Discard the precipitate.
   - (g) Freeze the grayish colloidal suspension at −20° C. in portions corresponding to the daily requirement. Before using, thaw it at 37° C.

   This extract gives a Quick prothrombin time in normal plasma of approximately 15 sec. When stored frozen at a temperature below − 20° C., the extract remains unchanged during several months.

   NOTE: There are a number of good thromboplastin preparations on the market which can be substituted for this human brain thromboplastin.
2. Veronal buffer, pH 7.35.
   - (a) To 570 ml. 0.1M sodium diethylbarbiturate add 430 ml. N/10 hydrochloric acid and 5.67 gm. sodium chloride.
   - (b) Dilute with an equal volume of 0.9% sodium chloride solution.
3. Diluting solution.
   - (a) To 800 ml. 0.9% sodium chloride solution add 200 ml. Veronal buffer pH 7.35 and 700 mg. potassium oxalate monohydrate.[298]
4. Calcium chloride solution. This is usually 0.03M, but optimal concentration must be determined for each batch of ox plasma.
5. Prothrombin-free and proconvertin-free ox plasma.
   - (a) Mix 9 vol. ox blood with 1 vol. 2.5% (w/v) potassium oxalate monohydrate solution and obtain plasma by centrifugation.
   - (b) Remove prothrombin by using asbestos paper filter pads containing 30% asbestos.
   - (c) Store plasma overnight at 0° C.
   - (d) Centrifuge to remove fatty material which tends to clog filters.
   - (e) Pass the plasma through a clarifying filter containing 20% asbestos and then once through filter paper pads containing 50% asbestos; 400 ml. plasma may be passed through a filter of 15 cm. diameter. When larger amounts are filtered, some prothrombin remains in the filtrate.
   - (f) Adjust the reaction of the plasma to pH 7.3 by adding N/2 hydrochloric acid.
   - (g) Store at −20° C. or lower temperatures in small bottles or glass tubes stoppered with corks in quantities suitable for 1 day's use.
6. Potassium oxalate solution, 2%.
   - (a) Dissolve 2 gm. potassium oxalate in distilled water and dilute to 100 ml. with distilled water.

Procedure:

1. Place 0.5 ml. 2% potassium oxalate in a test tube.
2. Add 4.5 ml. blood obtained by venipuncture and mix.
3. Centrifuge for 5 min. at 1000 r.p.m. and remove the plasma.
4. To 0.2 ml. plasma add 1.8 ml. diluting solution.
5. Place all the reagents in a water bath at 37° C.
6. Place 0.2 ml. prothrombin-free, convertin-free ox plasma in a small Kahn tube.
7. Add 0.2 ml. plasma dilution and 0.2 ml. thromboplastin.

8. Mix by shaking gently.
9. With a stop watch ready, blow out 0.2 ml. calcium chloride solution and begin timing.
10. Observe the end point for clotting.

Record the time as in Quick 1-stage method. Obtain the percentage from a correlation graph. Prepare the graph by serial dilutions of normal plasma, using diluting fluid, but maintaining a concentration of 100 mg.% oxalate.[298]

Comment: Owren believes that by following his procedure he maintains the following principles:

1. Determines combined effect of prothrombin and proconvertin.
2. Keeps a constant substrate of thromboplastin, calcium, proaccelerin, and fibrinogen, the latter 2 coming from the added adsorbed ox plasma.

He particularly points out that his P and P method is superior to previous methods in the control of Dicumarol therapy, in which the effect is a depression of the prothrombin and proconvertin values, leaving proaccelerin unaltered. In vitamin K deficiency and in liver disease, the same relationships hold although in the latter severe damage may cause a decrease in proaccelerin as well.

Specific determination of prothrombin—Owren[299]

The basic principle in this test is to keep the reaction mixture constant in the content of thromboplastin, calcium, proconvertin, proaccelerin, and fibrinogen.

Reagents: Reagents are the same as in the P and P method just described, with the addition of proconvertin solution.

1. Proconvertin.
   Proconvertin is obtained from human serum by adding a small amount (3 ml./100 ml. blood) of thromoplastin to venous blood, stirring immediately after withdrawal. This results in disappearance of prothrombin within 10-30 min. Storage at room temperature for 2 days causes accelerin to disappear.
2. Plasma-serum reagent.
   Mix the serum prepared as just given with equal parts of prothrombin-free and proconvertin-free ox plasma to make a plasma-serum reagent.

Procedure: The method is essentially that of the P and P method, with the following quantities used in this test:

0.2 ml. 1:10 dilution of test plasma.
0.4 ml. plasma-serum reagent.
0.2 ml. thromboplastin.
0.2 ml. calcium chloride.

Record the time required for clotting in this mixture. Calculate the percentage prothrombin by reference to a correlation graph prepared in a manner similar to that in the P and P method.

Comments: The major point about this modification is that it actually measures the activity of **prothrombin only,** whereas the usual one-stage modified Quick technics and the P and P method of Owren measure both prothrombin and proconvertin. In following patients with Dicumarol therapy, the P and P method is desirable because both prothrombin and proconvertin are affected. The determination of prothrombin only is a helpful tool in research.

Specific determination of proconvertin—Owren

The basic principle involved in this test is to keep the reaction mixture constant in thromboplastin, calcium, proaccelerin, prothrombin, and fibrinogen.

Reagents: The thromboplastin and calcium solutions are the same as in the P and P test (p. 1205).

Proconvertin-free ox plasma is prepared by filtering oxalated ox plasma through an asbestos filter pad containing only 20% asbestos.

Procedure: The procedure is essentially that of the P and P method, with the following quantities being used:

0.2 ml. proconvertin-free ox plasma.
0.2 ml. thromboplastin.
0.2 ml. unknown plasma diluted 1:20.
0.2 ml. calcium chloride.

Record the time required for clotting. Calculate the percentage proconvertin by reference to correlation graphs prepared from normal plasma diluted 1:20.

Comments: This determination has been a helpful tool in the investigation of clotting mechanisms. In clinical studies of bleeding diatheses, Alexander et al.[300] and Owren[302] and Aas[301] have described congenital hypoproconvertinemia. In 1953 Owren[302] described this defect as a congenital and hereditary defect. He points out that the whole clotting time in these patients may be normal or only slightly prolonged. The Quick prothrombin time was markedly prolonged, but vitamin K did not restore the hypoproconvertinemia to normal.

Specific determination of proaccelerin—Owren[301]

The basic principle involved in this test is to keep a reaction mixture constant in thromboplastin, calcium, prothrombin, proconvertin, and fibrinogen.

Proaccelerin-free plasma for the test is obtained by storage of adsorbed ox plasma or from a case of parahemophilia.

Procedure: The procedure is the same as in the P and P method (p. 1205), using the same concentrations of calcium chloride and thromboplastin with proaccelerin-free plasma.

Comments: This method has been helpful as an investigative tool in the study of clotting mechanisms. By this method, Owren in 1943 was able to detect the first verified case of parahemophilia (factor V deficiency) as a human congenital deficiency. Since then, other cases have been reported as either hereditary or congenital.

These clinical studies have given a new impetus to the study of hemophilia and hemophilia-like diseases.

Prothrombin consumption method—Quick[303]

Reagents:

1. Blood.
   - (a) Obtain 6 ml. blood by clean venipuncture, using 2-syringe silicone technic.
   - (b) Transfer 2 ml. samples to each of 3 tubes.
2. Deprothrombinized rabbit plasma.
   - (a) Mix 9 vol. freshly drawn rabbit blood with 1 vol. M/10 sodium oxalate.
   - (b) Obtain the plasma by centrifugation.
   - (c) Measure the plasma after withdrawing it from the blood cells.
   - (d) For each ml. oxalated plasma, place 2.5 ml. 0.005M suspension of tricalcium phosphate in a test tube.
   - (e) Centrifuge to pack the gelatinous calcium phosphate.
   - (f) Pour off the surplus water.
   - (g) Add the required vol. fresh oxalated plasma.
   - (h) Mix with the adsorbent.
   - (i) Stir repeatedly with a small glass rod for 5 min. at room temperature.
   - (j) Remove the calcium phosphate by centrifugation, pouring the clear adsorbed plasma into a clean test tube.
3. Thromboplastin solution.
   - (a) Incubate 0.2 gm. acetone-dehydrated rabbit brain with 5 ml. physiologic saline at 50° C. for 20 min.
4. Tricalcium phosphate, 0.005M.
   - (a) Dissolve 158 gm. trisodium phosphate in 1000 ml. distilled water.
   - (b) Dissolve 66.6 gm. anhydrous calcium chloride in 1000 ml. distilled water.
   - (c) Pour the calcium chloride solution into the trisodium phosphate solution with thorough stirring.
   - (d) Adjust the reaction to pH 7.0.
   - (e) Wash the precipitated tricalcium phosphate repeatedly by decantation until the sodium chloride is removed.
   - (f) Dilute to 1 L., thus making a 0.2M suspension.
   - (g) From this stock, a 0.005M solution can be prepared by mixing 2.5 ml. with 97.5 ml. distilled water.
5. 0.02M Calcium chloride.

Procedure:

1. Place the 2 ml. samples blood in a water bath at 37° C.
2. 15 minutes after clotting has occurred, remove tube 1, centrifuge at top speed for 1 min., and determine the serum prothrombin time by adding 0.1 ml. serum to a mixture of 0.1 ml. deprothrombinized rabbit plasma, 0.1 ml. thromboplastin, and 0.1 ml. calcium chloride solution.
3. Blow in the serum, and time.
4. Observe for clot formation and record time.
5. At the end of 30 min., centrifuge the second tube and perform a prothrombin time on this serum in the same manner as in the first tube.
6. Repeat the prothrombin time on the first tube at this time.
7. At the end of 45 min. recheck the prothrombin times of the sera in tubes 1 and 2.
8. At the end of 1 hr. centrifuge the third tube and make prothrombin time determinations on the sera of all 3 tubes.

Normal: 30-150 sec.

Comments: See comments on the simplified serum prothrombin test for the basic principles involved.

In this test the serum prothrombin time of normal blood ranges from 30-150 sec. The 3 tubes tend to show increasing times from the 15 min. test to the 1 hr. test. The testing of 3 tubes in the manner recommended serves as a control over the technic.

In hemophilia the times vary between 10 and 20 sec., with very little change in all 3 tubes. In thrombocytopenic purpura and thrombasthenia the average time is 25 sec. and in parahemophilia it is 34-38 sec.

Simplified serum prothrombin consumption test[304]

Materials:

1. Serum.

   Serum obtained from venous blood, using 2-syringe silicone technic and allowed to clot at room temperature. Place the blood in a water bath at 37° C. for 1 hr. after clotting. Centrifuge for 3 min. to separate the serum. Test the serum immediately or store at 4° C. for 1 hr. Do not use if stored more than 1 hr.
2. Thromboplastin solution.*

   Prepare as for plasma prothrombin time.
3. Fibrinogen solution.†

   This is to contain 300 mg.% fibrinogen in 0.85% sodium chloride solution.

For use: Just before the test, mix 2 ml. thromboplastin solution with 1 ml. fibrinogen.

Procedure:

1. Place all reagents in a water bath for 5 min.
2. Place 0.2 ml. fibrinogen-thromboplastin mixture in a clean dry test tube.
3. Add 0.1 ml. test serum to mixture by blowing it out of the pipet, simultaneously starting the timer.
4. Observe for clot formation, and time.

Normal: Longer than 30 sec.

Comments: The basic principle of this test and of the Quick prothrombin consumption test is that, in the normal process of clotting of blood, prothrombin is almost completely consumed, leaving serum with little residual prothrombin. If there is a deficiency of thromboplastin complex in a blood, prothrombin consumption is diminished, leaving a high prothrombin residual in the serum.

---

*Simplastin; Warner-Chilcott Laboratories, Morris Plains, N. J.

†Warner-Chilcott Laboratories, Morris Plains, N. J.

If to these sera are added optimal amounts of fibrinogen and thromboplastin, the time for a clot to form reflects the amounts of prothrombin present. In normal blood, the time is prolonged (beyond 30 sec.). A time of 20-30 sec. is considered doubtful, and anything below 20 sec. is indicative of thromboplastin deficiency.

In thrombocytopenia, whether primary or secondary, the test has yielded low values. This has been true of a case of thrombasthenia. Hemophilia and hemophilia-like diseases give a short serum prothrombin time. When heparin is administered, the serum prothrombin time becomes abnormally low. On the other hand, the coumarins have no effect on the serum prothrombin time since they do not depress thromboplastin complex.

Sources of error in prothrombin time estimations

1. The venipuncture must be clean.
2. The ratio between oxalate and blood must not be changed. Excess of oxalate will materially alter the results.
3. In centrifuging the blood, the correct time and speed are 5 min. at 2000 r.p.m.
4. Plasma should be removed from the cells as rapidly as possible after centrifuging.
5. Plasma must be kept refrigerated if not handled immediately.
6. The temperature of the water bath must be **exact.**
7. Plasma standing at 37° C. in a water bath loses 50% of its activity within 1 hr.
8. Any detergent used in cleaning glassware must be removed; if left on the glassware, even if only a very faint trace remains, it will interfere with the accuracy of the test.

Thrombotest[305-309]—Owren

After the introduction of the Owren P and P test it was discovered that the anticoagulants reduce not only prothrombin and factor VII but also factor IX. In an attempt to produce a sensitive test which would allow the clinician to follow a patient on anticoagulant therapy, Owren prepared an all-in-one reagent called thrombotest.

Thrombotest contains phospholipids (cephalin) from human brain or soya bean, calcium chloride, crude extracts of animal tissue (thromboplastin), and adsorbed bovine plasma from which factors VII, IX, and X and prothrombin have been removed. Factor V and fibrinogen remain. The test can be made on venous or capillary blood. At the present time, thrombotest reagents are available from only one manufacturer.* The reagent, already mixed, is supplied in lyophilized form and is reconstituted with distilled water for testing of capillary blood and with 3.2 mM calcium chloride for testing citrated blood. The result of this rapid and simple test is expressed as a percentage of normal read from a correlation curve prepared from dilutions of pooled normal plasma. **Normal blood clotting time** is 35-40 sec.

Comments on prothrombin time determinations

The determination of prothrombin time has become so much a part of daily clinical practice that it is now a household word in the physician's practice. The background development of this interest is typical of how investigations and investigators, great distances apart, are suddenly catalyzed. In fact, a greatly stimulated interest in all phases of coagulation can be said to begin with the epic discovery by Dam,[310] in 1929, that chicks developed a hemorrhagic syndrome on a synthetic diet.[311] By 1935, Dam[312] reached the conclusion that these chicks were suffering from a vitamin deficiency with a coagulation defect (Koagulation-vitamin or vitamin K). The calendar of events that followed are listed below:

1936: Chicks on artificial diet have prothrombin deficiency.[313] Quick's quantitative studies on chicks showed prothrombin deficiency; hemorrhage occurred at levels of 10% prothrombin; alfalfa restored chicks to normal.[314] Quick suggests hypoprothrombinemia of patients with obstructive jaundice is related to vitamin K deficiency.

1937: Quick[315] reports hypoprothrombinemia and hemorrhagic diathesis in patient with obstructive jaundice. Tried treatment with alfalfa but unsuccessful. Suggested combining bile salts with alfalfa.

1938-1939: Clinical application of Quick's suggestions.[316-318]

1939: Isolation of vitamin K by Doisy and his associates.[319-322]

1939-1940: Chemical structure of vitamin K[319-321, 323, 324] and its synthesis; vitamin K_a naphthaquinone.

1940: The race is on for therapeutic use of synthetic vitamin K.[325-328]

Many reviews of the story are available, and we heartily recommend Quick's review on the hemorrhagic diathesis of avitaminosis K[285] as exciting reading. To surgeons everywhere there came a very simple method of controlling distressing oozing of blood in the patient with obstructive jaundice. The administration of vitamin K to such patients has become so routine as to warrant little further comment. It was quite natural that other clinical states associated with a deficiency of vitamin K be sought; perhaps the other outstanding group is the hemorrhagic disease of newborn infants. Prophylactic treatment of the mother just prior to delivery has brought about the same striking results as with the jaundiced patient. It has become routine procedure in obstetrics to administer vitamin K during labor. Lesser in numbers involved are hypoprothrombinemic states associated with vitamin K deficiency due to the following disorders: (1) biliary fistula, (2) poor absorption from the gastrointestinal tract, as in ulcerative colitis, sprue, intestinal fistulae, intestinal obstruction, pellagra, and gastrocolic fistula, (3) artificial fever, (4) change of the intestinal flora by sulfonamides and antibiotics, and (5) liver disease.

---

*Nyegaard & Co., Oslo, Norway.

Just as prothrombin determinations may disclose a vitamin K deficiency, serial determinations are helpful in judging the efficacy of vitamin K therapy. If a given clinical state is due to avitaminosis K, administration of the vitamin parenterally or orally should result in a fairly prompt return of prothrombin to normal **provided that the liver function is normal.** This fact forms the basis of a liver function test in which standardized doses of vitamin K are administered and prothrombin time determinations are made subsequently.[285]

If a patient has hypoprothrombinemia which promptly responds to vitamin K therapy, he does **not** have severe liver damage. The corollary to this is that a poor response indicates either parenchymal liver disease or inadequate dosage.

An interesting situation has been reported in which patients apparently failed to respond to vitamin K therapy, and the condition was called idiopathic hypoprothrombinemia until all the facts became known. In all these patients self-medication with Dicumarol should be suspected.

As the saga of vitamin K deficiency was exploding, it was not at all surprising that Link and associates, with the guidance of Quick, promptly solved a mystery plaguing farmers since 1921. Cattle developed a hemorrhagic disease of serious economic proportions which attracted the attention of veterinarians and research men. The events which followed are listed below:

1922-1924: Schofield[329, 330] attributes disease to spoiled clover ingested by cattle and associated with abnormal blood clotting.

1937: Quick[314] demonstrates drop in prothrombin of cattle fed toxic sweet clover hay.

1941: Link and associates[331-333] isolate, identify, and synthesize active agents in sweet clover, 3,3′-methylenebis (4-hydroxycoumarin).

1941: Studies on effect of dicoumarin on human beings and experimental animals[334, 335]; the beginning of Dicumarol therapy.

Since these basic studies, anticoagulant therapy has been extensively used in the treatment of human disease associated with thrombosis.

Anticoagulant therapy

The patient, the laboratory technician, the pathologist, and the clinician should be familiar with the difficulties which may arise in the course of anticoagulant therapy. The clinician must know the interpretation and limitations of the various tests used to follow the course of the patient. The clinical pathologist and the laboratory technician should be familiar with the various anticoagulants—their indications, contraindications, control tests, and antidotes. Last, the patient should know the danger signs of uncontrolled self-medication and of unsupervised discontinuation of anticoagulant therapy.

Dicumarol

Two substances frequently used as clinical anticoagulants are Dicumarol (a coumarin derivative) and heparin.

Dicumarol (bishydroxycoumarin) (3,3′-methylenebis-4-hydroxycoumarin) has been well established as an adjunct in the management of thromboembolic disease. Perhaps its most universal application in clinical medicine has been in acute coronary thrombosis. Coronary occlusion has been known to be associated with the formation of mural thrombi which may serve as a nidus for emboli. Prophylactic administration of Dicumarol reduces the incidence of emboli considerably.

Wright et al.[336] come to the conclusion that all patients with myocardial infarction should receive anticoagulant therapy unless a contraindication to such therapy exists.

Schnur,[337] in a question-answer address read in a panel discussion on the use and abuse of anticoagulant therapy, pointed out that not all of the problems relating to such therapy are readily solved. He particularly indicated the difficulties of the clinical diagnosis of thromboembolism and even questioned whether postmortem examinations can fully reflect this feature of mural thrombi. He believes that the effective ranges of prothrombin at present are at best "educated guesses." His position is that of selective therapy rather than routine. This subject is pursued further by Russek and Zohman[338] who came to the following conclusion: "Anticoagulant therapy is neither necessary nor desirable for the large segment of patients who sustain their first attack of acute myocardial infarction and present no unfavorable criteria for recovery at the time of the first examination."*

Everyone is agreed that the use of anticoagulant therapy is based on a reduction of prothrombin time by Dicumarol and related drugs. Serial determination of the prothrombin time is the only adequate method of control of such therapy and there is no substitute known at present for such control. For this reason, anticoagulant therapy with Dicumarol and related compounds (Tromexan, Link's compound 63, Danilone, etc.) should not be considered unless daily prothrombin time determinations are available. The clinical picture, bleeding times, clotting times, and other clinical laboratory procedures for studying the coagulation status of patients are totally inadequate and should not be considered tools for measuring control of therapy. The purpose of rigid control is twofold, namely, (1) reaching and maintaining effective levels, and (2) avoiding the complication of hemorrhage. Wright and associates found a level of 11-23% prothrombin activity as the optimal range for therapeutic effect, and when this range was achieved, thromboembolic phenomena were at their lowest incidence. Prothrombin percentages lower than this range produced no added advantages. Their rule of thumb was a prothrombin time which was 2½ times the control if the latter was 12-14 sec. If dosage is inadequate and optimal levels are not achieved, benefits will be minimal.

Hemorrhage is the only known complication of Dicumarol therapy. In uncontrolled cases, hemorrhage may be fatal or reach serious proportions. In cases controlled by daily prothrombin times, hemorrhage is generally insignificant. The most common clinical manifestations of hemorrhage are hematuria, hemoptysis, hematemesis, and epistaxis. Bleeding from other sources may occur and in the uncontrolled cases may involve any organ system in the body. The occurrence of hemorrhagic phenomena is a signal for cessation of anticoagulant therapy and careful following of the prothrombin time and is an indication for active treatment to restore the value toward a safe level. The treatment consists of administration of water-soluble vitamin K in a dose of 60-72 mg. intravenously once or twice. In the presence of severe bleeding, 250-500 mg. vitamin K_1 oxide orally is recommended. Transfusions of whole fresh blood or plasma may be necessary in cases associated with severe hemorrhage. Transfusions should be considered not only to re-establish the prothrombin status but also may be necessary to correct the anemia resulting from blood loss.

There is considerable difference of opinion as to the method of choice in prothrombin determinations. In clinical practice, the aim is relative simplicity with good control. A critical survey of the present knowledge of this procedure leaves us with the impression that oversimplicity is nigh impossible if one is to achieve really good control. The modified dilution methods (modified Quick, or the P and P test of Owren) appear to answer the problem of adequate laboratory control. The literature covering methods and materials is so voluminous that a review of this aspect alone would be impossible here. Suffice it to say that whatever technic is employed, certain basic principles must be adhered to: (1) the technic should be followed scrupulously as directed by the author of the technic, (2) materials should be assayed carefully for potency, and (3) controls should be included in any determination. Perhaps some of the differences in clinical results are reflections of poor laboratory control rather than an index of failure of anticoagulant therapy. One objection to insistence on such high standards of laboratory control is that hospitalization becomes almost imperative in order to achieve this. The resultant economic strain on hospitalized patients is used as an argument against routine anticoagulant therapy. However, in disease as serious as coronary occlusion it is somewhat difficult to argue against this care, except perhaps in the mildest cases. Wright[339] argues against withholding anticoagulants because it is impossible to predict which patients might develop thromboembolic phenomena. He states: "Unfortunately such prophetic vision foresight has failed. It is more difficult to

---

*From Russek, H. I., and Zohman, B. I.: J.A.M.A. **156**:1130, 1954.

predict whether the course of a case will be mild or severe on the day of onset, when decisions regarding therapy must be made, than in retrospect, after the patient has been discharged from the hospital. If a physician waits until the first thromboembolic episode occurs, he may have a permanently disabled patient, as in the case of a hemiplegia due to an embolus to the brain, or a dead one."*

Dicumarol dosage is determined by routinely estimating the prothrombin activity prior to the initial dose.

If patients on anticoagulants require surgery for any reason whatsoever, the prothrombin time should be returned to normal before surgery to avoid hemorrhage.

In addition to the use of anticoagulant therapy in coronary thrombosis, it is recommended in the following conditions.

1. The majority of cases of thrombophlebitis regardless of origin, including recurrent idiopathic thrombophlebitis, postinfectious or posttraumatic. Wright[339] makes the interesting observation that thrombophlebitis that progresses relentlessly despite adequate therapeutic levels of the coumarin compounds should arouse the suspicion of malignancy. He cites 20 examples of persistence of migratory phlebitis refractory to adequate therapy. Carcinoma of the pancreas and liver are most commonly associated with distant thrombophlebitis, although other organs may also have such association.
2. The prevention of postoperative thromboembolic disease. Although statistics generally show a lower incidence of postoperative thrombophlebitis or embolus[340] in patients given prophylactic dicumarolization, there is some question as to the wisdom of such procedure **routinely,** and perhaps it should be reserved for selected cases in which there is a notoriously high incidence of postoperative thrombophlebitis, such as pelvic surgery.
3. Patients with acute embolic or thrombotic occlusion of the peripheral arteries from any of several causes.
4. Patients with recurrent embolization and atrial fibrillation such as occurs in rheumatic heart disease.
5. Postpartum patients with previous histories of recurrent thrombophlebitis.

Dicumarol therapy should be used with caution in the following conditions.

1. Severe malnutrition and cachexia.
2. Unusually prolonged menses or menorrhagia.
3. Patients with reduced prothrombin activity due to salicylates or paraaminosalicylic acid in large doses. If Dicumarol therapy appears of greater value in treating a particular patient, it is recommended withholding large dosages of these drugs which can of themselves reduce the prothrombin activity.
4. Patients under prolonged antibiotic or sulfonamide therapy in which changes in the intestinal flora affect vitamin K synthesis.
5. Severe hypertension.
6. In any patient with an initial lowered prothrombin activity unless the cause for such lowering can be well delineated and in itself does not constitute a contraindication to anticoagulant therapy.
7. In patients recently subjected to operations on the central nervous system.
8. In patients with fever. Animal experiments have shown an accentuated response in the presence of fever.

The stabilization of a patient receiving Dicumarol is not always easily accomplished because of the factors just mentioned, to which must be added the variations of absorption of an orally administered drug and the basic hypocoagulability or hypercoagulability of the plasma.

For recent reviews of the present-day concept of long-term anticoagulant therapy the reader is referred to the references at the end of this section.[341, 342]

The contraindications to anticoagulant therapy are the following.

1. **Inadequate facilities for prothrombin determinations.**
2. Patients with hemorrhagic diatheses, particularly in which prothrombin is affected directly or indirectly as a result of the disease. Hemophilia-like syndromes and the thrombocytopenic purpuras are obvious examples of such diseases. In the thrombopenic states the lowered platelet count may be primary or secondary. It is safe to say that any patient showing a defect of the coagulation mechanism should be eliminated from anticoagulant therapy.
3. Pregnancy in the second or third trimester.
4. Patients scheduled for immediate surgery.
5. Patients with moderately or fully advanced renal or liver disease.
6. Patients with jaundice due to biliary obstruction or hepatocellular disease.

---

*From Wright, I. S.: Circulation 5:161, 1952.

7. Patients under continuous tube drainage of the stomach or small intestine.

8. Patients with hemorrhage of the central nervous system.

9. Patients with ulcerating lesions (gastrointestinal tract) and granulomatous lesions.

Since the introduction of anticoagulant therapy with Dicumarol, other drugs have been found and studied. Tromexan or 3,3′-carboxymethylene bis-(4-hydroxycoumarin) ethyl ester is a recent derivative and, as its chemical structure indicates, is related to Dicumarol. Compound 63 of Link[343] is a 4-hydroxycoumarin which has also been used in man and animals. Another group of anticoagulants which have come into more recent use are indanedione derivatives, such as Danilone* (2-phenyl-1,3-indanedione) and Indon† (2-phenyl-1,3-indanedione). These 2 related compounds have a more rapid effect on the prothrombin activity both in lowering the level and in returning it to normal after cessation of therapy. The hypoprothrombinemia induced by them is more refractory to vitamin K therapy than the coumarin derivatives. Excellent comparative studies of these newer anticoagulants are to be found in the *Fourth and Fifth Conferences on Blood Clotting of the Josiah Macy, Jr., Foundation.*[344, 345]

Heparin

Heparin is a mucopolysaccharide that interacts with an albumin cofactor (albumin factor X of Quick) present in the plasma to form an anticoagulant which affects all 3 phases of clotting, as previously stated. It is mainly an antithrombin, but it also has antithromboplastic and antiprothrombin effects.

Heparin is used clinically (1) to initiate anticoagulant therapy to bridge the latent period before coumarin drugs become effective, (2) in combined therapy with Dicumarol, (3) in arterial thrombosis or arteriosclerosis, and (4) in patients with hypertension requiring anticoagulant therapy. The usual dose is effective for 3-8 hr. (except Depo-Heparin‡), but the drug is cumulative. Whole blood clotting time determinations are adequate to follow heparin therapy whether regular or Depo-Heparin‡ is used.

Heparin and postoperative thrombosis and embolism: Crafoord and Jorpes of Stockholm, Sweden, utilized heparin in attempting to prevent postoperative vascular thrombosis. In 325 patients treated with heparin no great complication occurred, whereas in the control series of 1111 similar cases, complications occurred in 9%. In Sweden 30,000 doses of heparin of 50-100 mg. each have been given intravenously without any fatalities or any noteworthy drawbacks.

Murray and Best found no thrombosis or embolism in 400 patients. Moreover patients with phlebitis were improved by treatment with heparin, and favorable effects of heparin in a small number of patients with pulmonary embolism were reported.

Two developments make it mandatory for the laboratory technician to understand the action and neutralization of heparin. (1) Heparin is the anticoagulant used in open heart surgery; its concentration must be evaluated, and, if necessary, its activity must be counteracted. (2) Quite recently heparin has been used because of its lipemia-clearing action. Lipemia is associated not only with an increased clotting tendency but also with arteriosclerosis so that heparin is suggested as a treatment of arteriosclerosis and its consequences in patients with lipemia. The standard dosage should not change the whole blood clotting time.

For heparin assay method, see discussion of methods for circulating anticoagulants.

The **antidote to heparin** is protamine sulfate or Polybrene* (hexadimethrine bromide).

Plasma fibrinogen assay

The plasma fibrinogen assay methods are described on p. 1227.

THROMBOPLASTIN TESTS

Thromboplastin generation test—Biggs, MacFarlane, and Miale

Principle: This test is essentially a 1-stage prothrombin test, but the thromboplastin added is not tissue (brain) extract but intrinsic plasma thromboplastin formed by the interaction of the patient's blood components: platelets, $Al(OH)_3$-adsorbed plasma (factors V and VIII), serum (factors VII and IX), and calcium. The thromboplastic activity is tested on a substrate consisting of platelet-poor plasma which contributes prothrombin and fibrinogen. Under these circumstances, the above mixture will produce a clotting time of 10 sec. or less after 5 min. incubation at 37° C. If the thromboplastin generation is defective, the clotting time may exceed 12 sec., or although it may be shorter, it will be delayed beyond 6 min. incubation. In the case of defective thromboplastin generation, the cause can be traced to one of the 3 main components of the system—serum, adsorbed plasma, or platelets—by substituting each one at a time into a normal system. Thus the activity of the patient's fraction can be compared with the activity of the normal control fraction. For instance, by substituting a suspension of unknown platelets for normal platelets, it can be determined whether the platelet function of the unknown blood is normal or deficient.

---

*Schieffelin & Co., New York, N. Y.

†Parke, Davis & Co., Detroit, Mich.

‡Upjohn Co., Kalamazoo, Mich.

*Abbott Laboratories, North Chicago, Ill.

Normal blood fractions are available commercially.*

Procedure†:

1. Collect blood using the 2-syringe silicone technic.
2. Place 3 ml. blood from the first syringe in a Kahn tube without anticoagulant but containing 3 glass beads.
3. From the second syringe, which is silicone-coated, add 4.5 ml. blood to a silicone-coated tube containing 0.5 ml. 3.8% sodium citrate and add 0.5 ml. blood to a second silicone-coated tube containing 0.5 ml. 0.1M sodium oxalate.
4. Cover each tube with Parafilm and invert repeatedly, thus ensuring clotting in the first tube and further mixing in the other 2 tubes.

Preparation of platelets and substrate plasma:

1. Centrifuge citrated blood at 1500 r.p.m. for 10 min. and then remove platelet-rich plasma.
2. Centrifuge platelet-rich plasma at 10,000 r.p.m. in an angle centrifuge for 5 min. and remove platelet-poor plasma, which furnishes the substrate plasma.
3. Suspend the remaining platelet button by stirring.

Alumina plasma:

1. Pipet 0.05 ml. $Al(OH)_3$ gel and 1 ml. platelet-poor plasma into a 13 × 100 mm. tube.
2. Mix continuously in a water bath for 3 min.
3. Centrifuge for 3 min. at 3000 r.p.m.

Patient's alumina plasma:

1. Transfer supernatant plasma to a clean test tube and label it **Alumina plasma.**
2. Determine 1-stage prothrombin time, which should be between 1 and 4 min.
3. If satisfactory, prepare a 1:5 dilution alumina plasma with saline, using 0.5 ml. alumina plasma plus 2 ml. saline.

Patient's serum:

1. 2 hr. after the blood in the tube with the glass beads is placed in a water bath, rim the clot and centrifuge for 10 min. at about 2000 r.p.m.
2. Aspirate the serum into a 13 × 100 mm. tube and label it **Patient's serum.**
3. Prepare 1:10 dilution of serum in saline solution by using 0.5 ml. serum and adding 4.5 ml. saline.

Control platelets, plasma, and serum may be obtained commercially.

Performance of test:

1. For each incubation mixture (combination of serum, plasma, and platelets) set up 6 Kahn tubes each containing 0.1 ml. substrate plasma, label 1-6, and place in a water bath at 37° C.
2. Also place in the water bath 2 tubes each containing about 4 ml. M/40 $CaCl_2$.
3. Prepare the first incubation mixture by using 0.3 ml. each of the 3 reagents (platelets, alumina plasma 1:5, and serum 1:10). The incubation mixture thus contains 0.9 ml. Place it in a water bath.
4. Add 0.3 ml. M/40 $CaCl_2$ to the incubation mixture and start an electric master interval timer. This is 0 time. Sample the mixture every min. for 6 min.
5. 1 min. after the $CaCl_2$ is added to the incubation mixture, add 0.1 ml. of the incubation mixture and 0.1 ml. $CaCl_2$ solution simultaneously with automatic pipets to the first tube of plasma substrate and start a second stopwatch immediately.
6. At 1 min. intervals, as determined from the master timer, transfer 0.1 ml. incubation mixture and 0.1 ml. $CaCl_2$ to successive tubes of substrate, starting a separate stopwatch for each tube when the incubation mixture and $CaCl_2$ are added.
7. Record the clotting time for each tube. The end point is the first appearance of a clot in each substrate tube, which is similar to the one seen in the prothrombin time determination.
8. Prepare different incubation mixtures and perform the 6 tests for each mixture.
9. Record on the worksheet the composition of the incubation mixtures, as well as the clotting times of the various tubes (Fig. 401).

Partial thromboplastin time (PTT)—Langdell et al.[349]

Materials:

1. 4.5 ml. blood obtained by clean venipuncture.
2. M/10 Sodium oxalate.
3. Partial thromboplastin.

   This may be crude cephalin or Asolectin.* The cephalin is prepared as a 0.3% suspension, the Asolectin as a 1% suspension. Adjust by dilution in saline to give a clotting time range of 40-80 sec. with normal plasma.

---

*TGTR; Warner-Chilcott Laboratories, Morris Plains, N. J.

†Method described is based partly on the description of the method for TGT in Mandel, E. E.: Workshop on techniques in blood coagulation, Chicago, 1960, American Society of Clinical Pathology, and partly on Miale, J. B.: Coagulation workshop book, Kansas City, 1959, American Society of Clinical Pathology.

Patient	Patient	Patient						

Fig. 401. Worksheet for thromboplastin generation test.

4. 0.02M Calcium chloride.

Procedure: The procedure is essentially that of the 1-stage prothrombin activity test.

1. Add 4.5 ml. venous blood to 0.5 ml. M/10 sodium oxalate.
2. Separate the plasma by centrifugation.
3. Keep all reagents at 37° C.
4. Mix in the following amounts and order: 0.1 ml. plasma, 0.1 ml. partial thromboplastin, and 0.1 ml. 0.02M calcium chloride.
5. Record the time in sec. for clotting to occur.

Normal: Normal values depend on concentration of thromboplastin used and are usually 40-80 sec.

Comments: The principle is that partial thromboplastins give a longer clotting time than complete thromboplastins, such as are used in routine prothrombin determinations. Langdell et al. found that complete thromboplastins clot normal and hemophiliac bloods equally fast. However, partial thromboplastins clot hemophiliac bloods less rapidly than normal bloods.

This test has been offered as a useful screening procedure in hemophiliac states.[280] It may be substituted for the prothrombin consumption tests described on p. 1207. Partial thromboplastin is available commercially[*]; therefore this test can be used more readily as a screening procedure for latent bleeders.[350]

Hicks-Pitney modification of TGT

This is a rapid simplified modification of the TGT which allows routine screening. Two commercial reagents, Platelin[†] and Diagnostic Plasma,[†] are required.

Reagents:

1. Platelin.
2. Diagnostic Plasma.
3. 0.025M Calcium chloride.
4. 0.1M Sodium oxalate or citrate.
5. Sodium chloride, 0.85%.

Preparation of reagents:

1. Reconstitute the Platelin by adding 2.5 ml. distilled or deionized water to the vial. Shake to ensure dispersion of the fine suspension.
2. Reconstitute the Diagnostic Plasma by adding 0.5 ml. distilled water. Swirl gently to dissolve. For multiple determinations, the large bacteriologic sized vial may be used: reconstitute with 2.5 ml. distilled water.
3. Dilute the patient's plasma to 10% by adding 0.1 ml. patient's plasma to 0.9 ml. 0.85% saline solution. Testing should be started within 5 min. of the dilution.

Procedure: Place the following in a water bath at 37° C.: test tube containing patient's diluted plasma, test tube containing Platelin, test tube containing 2 ml. 0.025M calcium chloride, empty test tube, 4 prothrombin time tubes, each containing 0.1 ml. 0.025M calcium chloride, and test tube containing Diagnostic Plasma.

The entire test is done in a 37° C. water bath. Two timers are required: one to measure the overall incubation period and the other for the individual prothrombin time determinations.

1. Into the empty test tube pipet in rapid succession 0.2 ml. each Platelin, patient's dilute plasma, and 0.025M $CaCl_2$. Start the incubation timer simultaneously with the addition of the $CaCl_2$. This is the generation mixture.
2. At 3 min. 45 sec., remove 0.1 ml. generation mixture and blow into one of the tubes containing 0.1 ml. 0.025M calcium chloride. **Do not** stop the incubation timer.
3. At 4 min., blow 0.1 ml. Diagnostic Plasma into the tube containing 0.1 ml. each of generation mixture and calcium chloride. Simultaneously, start the second timer and time the clot formation exactly as in the prothrombin time test.
4. At 5 min. 45 sec. repeat step 2.
5. At 6 min. repeat step 3.
6. At 7 min. 45 sec. repeat step 2.
7. At 8 min. repeat step 3.
8. At 9 min. 45 sec. repeat step 2.
9. At 10 min. repeat step 3.

When enough plasma thromboplastin has been generated to clot the Diagnostic Plasma in 16 sec. or less, stop the incubation timer and terminate the test.

Note: If a clot forms in the generation mixture tube at any time during the test, remove it to prevent interference with pipeting. **Do not** stop the incubation timer (a clot in the generation mixture has no bearing on the test).

---

[*] Ortho Pharmaceutical Corp., Raritan, N. J.

[†] Warner-Chilcott Laboratories, Morris Plains, N. J.

Results: If stage 1 is normal, incubating the generation mixture for 8-10 min. will generate enough plasma thromboplastin to give a 16 sec. prothrombin time with Diagnostic Plasma. If the Diagnostic Plasma does not clot in 16 sec. or less after 10 min. incubation of the generation mixture, one of the factors necessary to stage 1 of coagulation (plasma thromboplastin formation) is probably deficient in the patient's plasma. To pinpoint the specific defect, a TGT should be done and the results are interpreted according to the more definitive TGT.

TESTS FOR CIRCULATING ANTICOAGULANTS

Heparin assay—Quick[263]

Principle: In plasma, heparin acts as an antithrombin. If heparin is added to a standard solution of thrombin in oxalated plasma, the clotting time becomes proportional to the concentration of heparin.

Reagents:

1. Normal control blood.
   (a) Obtain blood by 2-syringe silicone technic and prepare oxalated plasma.
2. Thrombin, full strength.
   (a) Add 0.1 ml. thrombin to 0.2 ml. fresh oxalated plasma so that a clotting time of about 3 sec. is achieved.
3. Heparin.
   (a) Dissolve 100 mg. heparin in 10 ml. NaCl.
   (b) Add 0.25 ml. this solution to 50 ml. distilled water so that 1 ml. this solution contains 50γ heparin or that 0.01 ml. solution equals 0.5γ heparin.
4. Protamine sulfate.
   (a) Prepare 0.5% solution in 0.85% NaCl or 1% toluidine blue solution in distilled water.

Procedure:

1. Add 0.01 ml. heparin solution to 0.5 ml. fresh oxalated plasma.
2. After 5 min. incubation at 25° C., transfer 0.2 ml. this plasma to another test tube and incubate at 37° C. for 15 sec.
3. Blow 0.1 ml. thrombin solution into this plasma and determine the clotting time.
4. Repeat the test with 0.02, 0.03, 0.04, and 0.05 ml. heparin solution.

Average results are given in Table 242. These figures act as a base line for the following determinations.

Table 242

Heparin solution (ml.)*	0	0.01	0.02	0.03	0.04	0.05
Heparin concentration (γ)		1	2	3	4	5
Clotting time (sec.)	7	9	12	16	22	30

*Added to 0.5 ml. plasma.

Determination of heparin (or heparin-like substances) in blood[263]

To 0.2 ml. of patient's oxalated plasma, add 0.1 ml. thrombin solution and 0.01 ml. of physiologic saline solution. The control clotting time for this system was 9 sec. (see Table 242). If, for example, the patient's clotting time is 30 sec., then it must be determined whether the inhibitory substance is heparin by neutralizing it with protamine.

To 0.2 ml. patient's oxalated plasma, add 0.1 ml. thrombin solution and 0.01 ml. protamine sulfate (or toluidine blue solution). If in this system the clotting time now returns to 9 sec., the patient's blood contains 5 μg heparin.

Fibrinolysis

Simple screening test for increased fibrinolysis—Stefanini-Dameshek

Equipment: The equipment is the same as that used for thrombin time, plus purified bovine fibrinogen, 600 mg./100 ml. saline (optional).

Procedure:

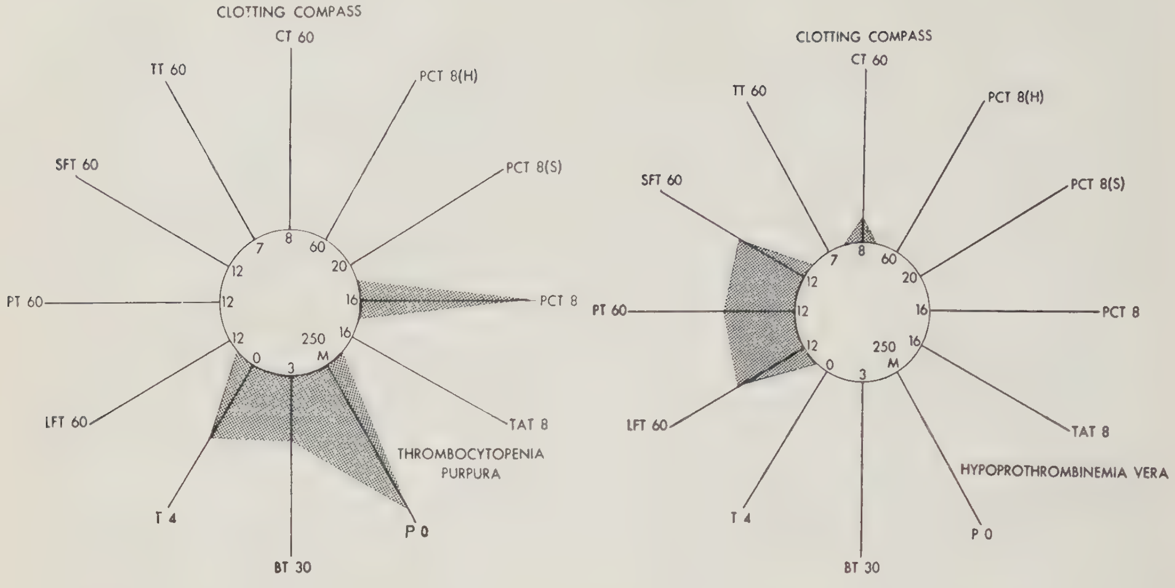
1. Prepare platelet-poor plasma from citrated venous blood collected from both the patient and a control subject by adding 4.5 ml. venous blood to 0.5 ml. 3.8% sodium citrate. Centrifuge slowly for 10 min., obtain platelet-rich supernatant fluid, and centrifuge this at high speed for 30 min.
2. Maintain ice-water temperature from the moment of venipuncture and allow no delay between steps in procedure.
3. From each of the 2 plasmas transfer 0.5 ml. to a cold test tube and mix. In addition, place 1 ml. each plasma in separate tubes.
4. Transfer all 3 tubes from the ice bath to a 37° C. bath, add to each 0.1 ml. saline solution containing 10 units of thrombin, and mix immediately.
5. Observe each clot at frequent intervals (at least every 30 min. for the first 6 hr.) for detection of complete lysis.

Normally no noticeable lysis occurs in 24 hr. Lysis time can be shortened and the test can be made more convenient by substituting for normal plasma purified bovine fibrinogen, which contains little antifibrinolysin.

The assay of fibrinolytic activity will be an important test in the future if fibrinolytic agents such as human fibrinolysin or streptokinase prove successful in the treatment of recent thromboses. Experimental methods are suggested in the references.[351-353]

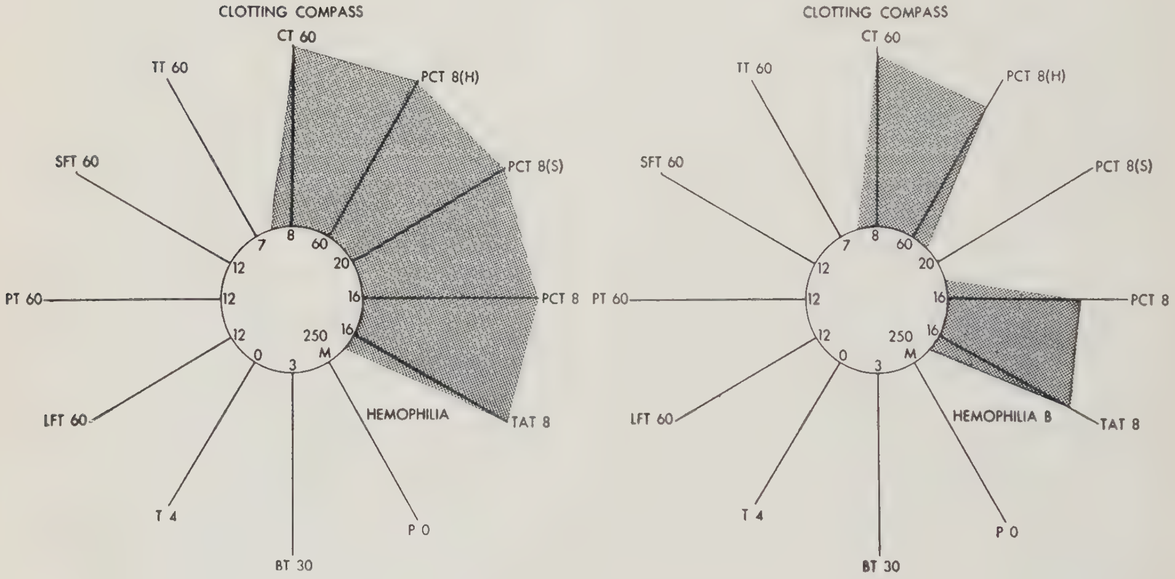
CLOTTING COMPASS

On the basis of the coagulogram of Gerendas, Quick[354] designed the clotting compass (Figs. 402 and 403) to provide a diagrammatic presentation of the clotting defects in various hemorrhagic diseases. This approach allows easy visualization and ready comparison of the clotting pattern and consists of the various tests described in the preceding pages.



A B

Fig. 402. **A,** Clotting compass in thrombocytopenic purpura. **B,** Clotting compass in hypoprothrombinemia. (From Quick, A. J.: Thromb. diath. haemorrhag. **3**:302, 1959.)



A B

Fig. 403. **A,** Clotting compass in hemophilia. **B,** Clotting compass in hemophilia B. (From Quick, A. J.: Thromb. diath. haemorrhag. **3**:302, 1959.)

The patterns of some of the hemorrhagic disorders are reproduced. The lines representing the tests radiate from an inner circle corresponding to the normal values of the methods. The distal points in the periphery represent the maximal abnormal values. The following abbreviations are used.

CT = clotting time
PCT(H) = prothrombin consumption time with hemolysate
PCT(S) = prothrombin consumption time with serum
PCT = prothrombin consumption time
TAT = thromboplastinogen activity time
P = platelet count
BT = bleeding time
T = tourniquet test
LFT = labile factor time
PT = prothrombin time
SFT = stable factor time
TT = thrombin time

HEMOSTASIS AND ABNORMALITIES OF BLOOD COAGULATION

In the normal individual, blood courses through the vascular tree in a properly fluid state, carrying a multiplicity of substances and structures. Life itself is dependent upon the complex regulatory mechanisms that maintain an exquisite balance of all the factors which combine to make for this state of normality. A basic requirement for sustaining such a status quo is an intact vascular system which, while maintaining its integrity, still permits selective exchanges of vital materials between the circulatory system and the tissues. Although a great deal of knowledge has been accumulated concerning capillaries, there is perhaps more information concerning their reaction to injury and in disease than answers as to why they remain intact in the normal individual. Alterations in the character of the vascular bed may occur as the result of a multiplicity of causes, involving direct and indirect assault on the vessels themselves or on the contents of the vessels. The end result of such attacks may be the escape of blood from the vessels or the closure of vessels. It is quite apparent from these remarks that the study of any patient in whom the defense mechanisms for maintaining the normal liquid state of blood in an intact vascular system have been threatened involves consideration of many factors. These might be conveniently considered under the following general headings: (1) the state of the vascular tree, (2) the state of the coagulation mechanism, and (3) the status of tissues and organs related to the elaboration of elements essential to maintaining normal coagulability of blood, notably the liver, spleen, and bone marrow.

Alterations in one or in combinations of these basic states may result in either hemorrhagic diathesis or thrombosis. The clinical results of such derangements cover the entire spectrum from mild symptoms to fatal outcome. In the study of patients with any such symptoms, consideration of the causes involves complete history, physical examination, and laboratory examination. As in all clinical medicine, we cannot emphasize too strongly the need for thorough history taking and physical examinations **before** rushing to the laboratory for answers to such patients' problems. This orderly procedure will often circumscribe the disease process and eliminate the necessity of costly and time-consuming laboratory tests.

The **history** should completely consider the family history as well as the personal history of the patient. In hemorrhagic diseases, hemophilia is undoubtedly the outstanding example. As knowledge of the factors involved in hemostasis has grown, many other examples of hereditary disease have been uncovered. Following is a list of diseases in which heredity plays a role.*

HEMORRHAGIC DISEASES

Hereditary hemorrhagic diseases

Capillary purpura due to congenital abnormalities of vascular wall
  Hereditary capillary fragility (pseudohemophilia, purpura of capillary weakness, von Willebrand's disease)
  Hereditary capillary telangiectasia (Rendu-Weber-Osler disease, Goldstein's heredofamilial angiomatosis, hereditary angiomata, hereditary hemorrhagic telangiectasia)

Thrombocytopenic purpura due to
  Hereditary thrombocytopenia
  Thrombocytopathic purpura
  (Glanzmann's thrombasthenia)
  Hegglin's syndrome

Plasma defects affecting coagulation due to congenital deficiencies
  Congenital hypoprothrombinemia
  Congenital fibrinogenopenia
  Congenital deficiency of antihemophilic globulin (AHG)

---

*This list is based on the recommended nomenclature published by a committee sponsored by the American Medical Association and the American Society of Clinical Pathologists (Am. J. Clin. Path. 20:575, 1950). The designations appearing in parentheses are synonymous terms found in the literature but which this committee recommends avoiding. Minor additions to the original list have been made by the author.

- Congenital deficiency of plasma thromboplastin component (PTC)
- Congenital deficiency of plasma thromboplastin antecedent (PTA)
- Congenital deficiency of accelerator factor (factor V deficiency, labile factor deficiency, plasma Ac-globulin deficiency, parahemophilia)

In the personal history of the patient suffering from one of the hemorrhagic diatheses, many possibilities of acquired disease other than obvious trauma are to be considered. For the purpose of orientation as to the multiplicity of these factors, the following list has been compiled.

- Capillary purpura due to increased vascular permeability and fragility
  - Mechanical cause
  - Infection (toxic purpura, Waterhouse-Friderichsen syndrome)
  - Emboli
  - Drugs
  - Allergy (anaphylactoid) (Schönlein's purpura, purpura abdominalis, Henoch's purpura, anaphylactoid purpura, purpura rheumatica, peliosis rheumatica, hemorrhagic capillary toxicosis)
  - Metabolic disturbances
    - Anoxia
    - Vitamin deficiency (scorbutic purpura, rutin deficiency)
    - Uremia
    - Senility
    - Endocrine (Ehlers-Danlos syndrome?)
  - Neoplasms
    - Leukemia
    - Hemorrhagic sarcoma (Kaposi's sarcoma)

- Thrombocytopenic purpura (Werlhof's disease, purpura hemorrhagica, primary or essential thrombocytopenia) due to
  - Idiopathic thrombocytopenic purpura (ITP)
  - Thrombotic thrombocytopenia (Moschcowitz's syndrome)
  - Thrombocytic hypoplasia from endocrine disturbance or irradiation
  - Drugs
  - Allergy
  - Myelophthisis from unknown cause, bone marrow replacement by tumor, leukemia, fibrous tissue, etc., or bone marrow aplasia (hypoplastic and aplastic anemias)
  - Infection

- Splenic disease or hypersplenism due to
  - Congestion
  - Lipid histiocytosis
  - Sarcoidosis
  - Tuberculosis
  - Neoplasm, primary or secondary
  - Leukemia
  - Liver disease
  - Acquired antibodies
- Thrombocytopenia associated with congenital hemangioma
- Qualitative platelet deficiencies (thrombocytoasthenia)
- Nutritional deficiencies, e.g., pernicious anemia

- Plasma defects affecting coagulation, acquired
  - Hypoprothrombinemia
    - Vitamin K deficiency
      - Of newborn (melena neonatorum, hemophilia neonatorum, morbus hemorrhagica neonatorum)
      - Deficient absorption from gastrointestinal tract
      - Obstructive jaundice
      - Steatorrhea
      - Drugs
    - Liver disease (pseudohemophilia hepatica)
    - Drugs, particularly Dicumarol (sweet clover disease)
  - Fibrinogenopenia due to liver disease
  - Endogenous anticoagulant
    - Drugs, especially heparin
    - Leukemia
    - Radiation
    - Venoms of snakes

- Circulating anticoagulants
  - Antithromboplastin
  - Antithrombin
  - Increased fibrinolysis

- Dysproteinemias
  - Multiple myeloma
  - Macroglobulinemia
  - Amyloidosis
  - Hyperglobulinemia

Although this list appears formidable, an adequate history oriented along these lines may be very fruitful. Wearing of tight garters or other restraining garments may be the source of mechanical purpura. At times the investigation need go no farther than observation of such patients without this apparel. The complete disappearance of symptoms on this regimen is generally sufficient proof of the causal factor.

Hemorrhagic diseases due to vascular defects

Vascular defects are 2-fold: increased permeability, such as occurs in vitamin C deficiency (ground substance defect) or increased fragility, which may be congenital or related to platelet deficiency or plasma factor deficiencies. Whatever the etiology there must be a vascular defect before bleeding from a blood vessel can occur.

For the purpose of description and classification it is best to separate the purely vascular purpuras from those caused by platelet or plasma factor deficiencies, though in some cases there may be some overlap.

Congenital vascular abnormalities

Congenital vascular abnormalities include hereditary hemorrhagic telangiectasia and pulmonary hemosiderosis. The latter is described in the discussion of iron-deficiency anemias.

The first disease shows dilatation and thinning of patchy collections of capillaries, frequently leading to bleeding from the nose and lung though bleeding may occur from the gastrointestinal and genitourinary tract.

Increased vascular permeability

Scurvy: Purpura is produced by increased vascular permeability due to vitamin C deficiency resulting in defective endothelial cement substance. Clinically important is the gingival bleeding which may point toward this condition. Vitamin P (hesperidin) deficiency may also lead to capillary oozing.

Increased vascular fragility

Some of the most frequently seen hemorrhagic tendencies are included in this classification. Ecchymoses and purpuric spots appear in the skin and frequently spare the mucous membranes. In simple hereditary purpura, in senility, in some endocrine disturbances such as Cushing's disease, cortisone administration, and menopause, in the course of infections, in toxemias such as uremia and diabetes, and after prolonged standing (orthostatic), the vessel walls are damaged and allow blood to escape. Similar damage may result from drug administration (see discussion of thrombocytopenias). Schönlein-Henoch purpura is an allergic or infectious form of purpura which has received special attention.

Schönlein-Henoch purpura

This disease is also referred to as allergic purpura or nonthrombocytopenic purpura. It is characterized by an urticaria-like eruption associated with petechiae and gastrointestinal symptoms (Henoch's purpura). It may also be accompanied by painful swelling of the joints (Schönlein's purpura rheumatica) and involvement of the kidneys. As the individual case may combine features of both, the disease is usually called Schönlein-Henoch purpura. Although the allergic nature of the disease is generally accepted, it appears to be extremely difficult in an individual case to discover the allergen. The allergen may be a bacterial toxin (streptococcal ?) or foods such as eggs, milk, and chocolate. Clinically important are the renal complications which produce a picture similar to that seen in glomerulonephritis or in some of the collagen diseases.

Laboratory findings in vascular defects

Bleeding time: Prolonged.
Coagulation time: Normal.
Clot retraction: Normal.
Tourniquet test: Positive.
Prothrombin time: Normal.
Prothrombin consumption time: Normal.
See also discussion of hematologic methods.

DEFECTS IN THROMBOCYTOPOIESIS

Both the increase (**thrombocythemia**) and the decrease (**thrombocytopenia**) in the number of platelets may be accompanied by hemorrhagic phenomena. Evidence of bleeding may also be seen when the platelets, though normal in number, are qualitatively inadequate (**thrombocytoasthenia**). In Chapter 62 conclusive proof was offered that the megakaryocytes of bone marrow produce platelets. Platelet changes may be associated with normal, decreased, increased, and qualitatively altered megakaryocytes.

Thrombocythemias

An increase in platelets is always associated with an increase in megakaryocytes (**megakaryocytosis**). As previously discussed, variations in the number of megakaryocytes are better appreciated in bone marrow sections than in bone marrow smears. Two types of thrombocythemias can be distinguished: (1) primary thrombocythemia, which may be seen in such myeloproliferative disorders as chronic myelogenous leukemia, polycythemia, myelofibrosis, and essential thrombocythemia (platelet or megakaryocytic leukemia) and (2) secondary thrombocythemia, which may be seen in multiple thrombosis, agranulocytosis, after hemorrhage, and after splenectomy.

Primary thrombocythemia

There is a marked variation in size of platelets from microplatelets to giant platelets and an increase in the number of thrombocytes up to 1 million or more, associated with a moderate rise in the total white and red blood cell counts. On clinical examination, splenomegaly is noted. There is a tendency to both thrombus formation on the one hand and bleeding on the other. The hemorrhagic phenomena are due to qualitative platelet changes. These changes may include a platelet factor 3 deficiency, or some difficulty in platelet disintegration (pachyderm platelets), or both, so that the thromboplastin generation test is abnormal when the patient's platelets are utilized. Phase microscopy examination of the platelets reveals absence of pseudopod formation and spreading, suggesting an intercellular enzymatic defect. The bone marrow shows a marked increase in normal to ab-

normal megakaryocytes surrounded by thick coats of various-sized platelets.

There may be some difficulty in distinguishing this platelet disease from forms of myeloproliferative disorders associated with a marked increase in platelets.

Thrombasthenia

Glanzmann (1918) first described a case with a normal number of platelets but with qualitative abnormalities leading to hemorrhagic manifestations. Electron microscopic examination of these platelets again shows a defect in pseudopod formation and in spreading in some cases, whereas other cases show excessive spreading. Abnormal viscous metamorphosis has also been noted, as well as diminution in certain enzymes such as glyceraldehyde phosphate dehydrogenase and pyruvatekinase. Secondary thrombasthenia has been reported in liver disease.

Thrombocytopenia[360-365]

Clinically thrombocytopenia leads to petechial hemorrhages involving the skin and mucous membranes so that internal hemorrhages are a frequent complication.

Three general classifications are distinguished: (1) thrombocytopenia due to defects in platelet production (amegakaryocytic form of Dameshek), (2) thrombocytopenia due to defects in platelet maturation, and (3) thrombocytopenia due to excessive peripheral destruction of platelets (megakaryocytic type of Dameshek).

Defects in platelet production

Amegakaryocytic thrombocytopenia

The following defects in platelet production are included in this type of thrombocytopenia:

- Congenital absence of megakaryocytes
- Bone marrow failure in aplastic anemia
- Bone marrow replacement by carcinoma, leukemia, lymphomas, etc.
- Toxic depression of megakaryocytes in severe infections and radiation therapy and by drugs (benzol, quinidine, etc.) acting directly on megakaryocytes

Defects in platelet maturation

Defects in platelet maturation occur in the following conditions:

- Pernicious anemia, which produces abnormal megakaryocytes and platelets
- Hegglin's syndrome, which involves polymorphonuclear cells and platelets
- Hypersplenism producing splenic thrombocytopenia either due to hormonal action or to antibodies, which act on platelets or megakaryocytes
- Congenital afibrinogenemia associated with thrombocytopenia
- Aldrich's syndrome (thrombocytopenia, eczema, and recurrent infection in infants and children)
- Paroxysmal nocturnal hemoglobinemia

Excessive destruction of platelets

Immune thrombocytopenias

Immune thrombocytopenias may be classified according to clinical course or according to etiology, as follows:

- *Classification according to clinical course*
  - Acute
  - Chronic
- *Classification according to etiology*
  - Allergic reactions
    - Drugs: quinine, quinidine, Sedormid, sulfonamides, digitoxin, mercury compounds, and codeine
    - Bacterial and viral infections
    - Waterhouse-Friderichsen syndrome
    - Dysproteinemias: lupus erythematosus and other collagen diseases
    - Hypersplenism
    - Hemolytic anemias
    - Idiopathic conditions: idiopathic thrombocytopenic purpura, isoimmune mechanism following multiple blood transfusions and during pregnancy and neonatal thrombocytopenia

Recently Cohen and others have reclassified thrombocytopenia by the Cr^{51}-labeling method for measuring platelet life span in newly diagnosed patients who did not receive transfusion, as follows:

Classification according to life span of Cr^{51}-labeled platelets

- Primary production deficit with normal life span
  - Various types of Dameshek's amegakaryocytic thrombocytopenia
  - Paroxysmal nocturnal hematuria
- Production deficit predominates but some shortening of life span present
  - Defects in platelet maturation of preceding classification
  - Nonimmune idiopathic thrombocytopenia
- Peripheral destruction predominates but relative production deficit sometimes present
  - Associated with megakaryocytic hyperplasia
    - Acute childhood immune idiopathic thrombocytopenia
    - Acute and chronic adult immune idiopathic thrombocytopenia
    - Immune thrombocytopenia secondary to lupus erythematosus
    - Drug-induced thrombocytopenia (quinidine-Sedormid prototype)
    - Compensated thrombocytopenia
      - Postsplenectomy idiopathic thrombocytopenic purpura
      - Postsplenectomy Felty's syndrome
      - Corticosteroid remission in idiopathic thrombocytopenic purpura
    - Granulomatous disease of the spleen
      - Sarcoidosis
      - Tuberculosis
    - Reticuloendothelial hyperplasia of the spleen not caused by portal hypertension
      - Felty's syndrome
      - Infectious mononucleosis
      - Acquired idiopathic hemolytic anemia (Evan's syndrome)
    - Myeloid metaplasia with massive splenomegaly
    - Thrombotic thrombocytopenic purpura
  - Associated with normal or reduced bone marrow megakaryocytes
    - Lymphosarcoma
    - Chronic granulocytic leukemia with massive splenomegaly
    - Thrombotic thrombocytopenic purpura

Platelets are proteinaceous and therefore antigenic. They contain blood group substances A and B, as well as up to 8 serologically different platelet antigens. There is some evidence that the contents of the A and B blood groups is simply adsorbed on the surface of the platelets.

Antibodies involved in immune thrombocytopenia may be shared with other cellular elements (red blood cells, white blood cells, etc.), they may be specific platelet antibodies, or they may be isoantibodies, immune antibodies, or autoantibodies. All may be either warm or cold in type.

Immune mechanisms

Several types of immune mechanisms may be responsible for platelet destruction. In the thrombocytopenia following administration of drugs or infections, it is thought that a hapten combines with the platelets to form an antigenically active hapten-platelet complex. These antigenically modified platelets agglutinate and are destroyed.

It is also possible that the hapten attaches itself to a plasma protein, and it is this hapten-plasma-protein complex which is antigenically active. If the patient is re-exposed to the original drug or infecting organism, the antibody attaches itself to the platelets, which are thus altered or destroyed.

Damage to the platelets may result from antigen-antibody reactions not primarily directed against platelets but primarily involving other cellular elements. This reaction which requires complement or an additional plasma factor, at least experimentally, leads to the release of histamine and of 5-hydroxytryptamine. This type of mechanism may be responsible for the symptomatic thrombocytopenias secondary to other diseases, e.g., leukemia, collagen diseases, etc.

Last, the antibody may be a specific platelet antibody acting on normal platelets. The thus sensitized platelets are agglutinated and destroyed by the reticuloendothelial system. In the presence of complement, they may be lysed. This mechanism is probably operative in isoimmune thrombocytopenias (following blood transfusions, etc.).

The platelets, damaged by the immune mechanism, are destroyed in the spleen. There is some evidence that the antiplatelet antibodies may also have some anticapillary or antiendothelial action which would be responsible for the purpura. Some of the platelet antibodies may also act directly on the megakaryocytes in the bone marrow because they share certain antigens with the platelets and damage them.

Idiopathic thrombocytopenic purpura (ITP)

Clinically idiopathic thrombocytopenic purpura is divided into an acute form which most frequently occurs in children and into a chronic form which is more common in adults. Both forms have in common thrombocytopenia in peripheral blood and normal or increased megakaryocytes in bone marrow, most of which are not platelet-producing.

Acute idiopathic thrombocytopenic purpura: This disease occurs most frequently in children who suddenly break out with petechiae involving the skin and mucous membranes. The platelet count is extremely low, less than 10,000, but the platelet morphology is more or less normal. Eosinophilia and lymphocytosis may be present. The bone marrow contains the usual number of megakaryocytes, most of which are young, are not platelet-producing, and show evidence of degeneration.

Chronic idiopathic thrombocytopenic purpura: As the name implies, this disease may last for years, interrupted by remissions. The platelet count is moderately low, less than 50,000. The bone marrow contains an increased number of mature megakaryocytes which show diminished platelet production. Platelet agglutinins are present in about 50% of the cases.

Pathogenesis of idiopathic thrombocytopenic purpura: For many years some splenic factor acting on the bone marrow was considered to be the etiologic agent since splenectomy frequently leads to an improvement in the clinical condition and the bone marrow. In recent years the immunoallergic theory has found more and more supporters. In about 50-70% of the cases of idiopathic thrombocytopenic purpura, Harrington has proved the existence of antithrombocytic antibodies, agglutinins, and lysins.

Harrington[355] has summarized the clinical significance of the antibodies for platelets, pointing out (1) that these agglutinins play a major role in the production of the thrombocytopenic state, (2) that platelet agglutinins may appear after repeated transfusions, and (3) that platelet agglutinins may appear as a sequela of pregnancy. The initial phase of Harrington's research in this field is a dramatic story which has opened the door to a brilliant research problem. To prove that the plasmas of patients with idiopathic thrombocytopenic purpura have a plasma factor which will induce thrombocytopenia, he had injected into himself such plasma and promptly experienced the clinical and hematologic picture of thrombocytopenic purpura.

From this beginning, the experiments have been elaborated both in vivo and in vitro. In 72 patients with idiopathic thrombocytopenic purpura, he found 50 who showed positive agglutinins and 22 who were negative for agglutinins. In the acute cases 30 out of 43 were positive, and in the chronic variety 20 out of 29 were positive for agglutinins. Auto-

agglutinins were not tested in all of these cases because in some instances only serum was available, but when both platelets and serum of the patients were available, two-thirds of the cases (27) showed autoantibodies. In addition to idiopathic thrombocytopenic purpura, autoantibodies were demonstrated in 2 cases of chronic lymphocytic leukemia, 2 cases of lupus erythematosus disseminata, a case of carcinomatosis, a case of atypical acquired hemolytic anemia, and a case of drug sensitivity. These cases represent 7 out of 13 controls with secondary thrombocytopenia in whom it was possible to test for autoantibodies. In this group of secondary thrombocytopenias, 28 out of 57 patients tested showed positive agglutinins in their sera. However, these agglutinins included both isoagglutinins and autoagglutinins. Of importance here is that only 3 out of the 28 patients with positive reactions had never been transfused or been pregnant. The significance of previous pregnancy or transfusions will be discussed presently. In 144 cases of nonthrombocytopenic controls, only 16 displayed agglutinins of any kind, but only 2 of these 16 had never been transfused nor pregnant. In 75 patients of the nonthrombopenic control group, there was not a single instance in which autoagglutinins were found. The patients within these control groups with positive agglutinins are considered chiefly as examples of isoimmunization, the isoagglutination occurring mainly as the result of multiple transfusions.

Harrington et al.[356] have reported 8 types of platelets; others[357] recognize 4 groups of serologically distinct platelet groups. These various platelet types have antigenicity in the same way as red cell types, and transfusions of mismatched platelets will result in antibody formation. Apparently, isoagglutinins for platelets can also be induced during pregnancy in a manner similar to that responsible for Rh incompatibility between the mother and the fetus.

The finding of autoantibodies in the blood of patients with thrombocytopenic purpura poses a number of questions. Clinicians have constantly been in search of criteria for splenectomy in these patients, and serologic tests of the type being discussed here were immediately looked upon as possible aids in this direction. Thirty-eight out of the 50 patients with positive agglutinins were splenectomized. Twenty-five of these had a complete remission, 4 patients had a partial remission, and the remaining 9 were not benefited by surgery. In the group of 22 patients without demonstrable agglutinins, 16 were splenectomized with the following results: 2 complete remission, 4 partial remission, and 10 not benefited. Although these figures indicate that the prognosis with splenectomy is apparently better when agglutinins are demonstrable, Harrington cautions that "more experience is needed, however, before it would be permissible to state with certainty that the presence or absence of platelet agglutinins should be a major criterion for the selection of candidates for splenectomy."*

Autoantibodies in a mother may result in neonatal thrombocytopenia in infants; Harrington cites 9 such cases. This may occur even though a remission has been induced in the mother by splenectomy. Harrington questions the utility of platelet transfusions in patients showing autoantibodies since platelets disappear readily from the circulation of such patients. He would reserve such measures only as temporizing in patients presenting serious hemorrhage intracranially or within the gastrointestinal tract. Harrington warns against the use of patients with a history of thrombocytopenic purpura as blood donors since antibodies may persist for years even though remission has been induced by splenectomy.

Isoimmunization may create problems akin to autoimmunization. Since multiple transfusions may induce isoimmunization, individuals receiving such transfusions should be screened as future donors of whole blood or plasma. Isoimmunization may occur in pregnancy, as previously noted. Harrington suggests: "Rejection of all candidates (for blood donors) who have received more than 20 transfusions of whole blood or anyone who has been transfused or pregnant within one year would seem to be reasonable minimum precautions at the present time."* Harrington points out the lack of feasibility of protracted platelet transfusions in patients with thrombocytopenic purpura especially of the secondary type; these patients develop isoimmunization and even refractoriness after 3 to 6 such transfusions and further pursuit of such therapy is valueless.

A third problem related to isoimmunization is primary neonatal isoimmunization occurring in infants born to mothers who have not had thrombocytopenic purpura. Isoimmunization

---

*From Harrington, W., et al.: Ann. Int. Med. **38:** 433, 1953.

in the mother may have come about through previous transfusions, pregnancy, or both. Such isoimmunizations correspond to that seen with Rh incompatibility in that the mother displays no symptoms.

As technics improve, agglutinin detection in the thrombopenic states will improve. Adelson and Stefanini[358] describe a heterologous (Forssman) type of platelet agglutinin in the case of thrombotic thrombocytopenic purpura. Phase contrast microscopy studies[359] of the bone marrow of normal recipients of plasma from a patient with a high-titer platelet agglutinin revealed changes in the megakaryocytes of the recipients similar to those seen in idiopathic thrombocytopenic purpura. These observations suggest that the antiplatelet factor acts by (1) attacking platelets being discharged from megakaryocytes, (2) preventing normal platelet formation from megakaryocytes, and (3) causing maturation arrest of megakaryocytes.

Laboratory methods in investigation of thrombocytopenic purpura

Platelet count

The platelet count is described in the discussion of platelets.

*Platelet agglutination test**

Reagents:

1. Silicone.
2. Ethylene diamine tetraacetic acid, disodium salt, 5%, in distilled water.

Materials:

1. 18-gauge needle.
2. 16 × 100 mm. test tubes.
3. 10 × 75 mm. test tubes.
4. Parafilm.
5. Broad-bore 1 ml. pipets graduated in tenths.
6. 37° C. water bath, 56° C. water bath.
7. Mechanical serologic rotating platform.
8. Depressed cell slides.

All glassware that comes into contact with platelets is siliconized. Needles are not coated.

Procedure:

1. Add 10 ml. blood for platelet suspensions to 0.4 ml. EDTA. Obtain blood from donors compatible with the test sera. It is good practice to use Group O donors whose platelets do not agglutinate readily. Some normal donors have platelets which require much care to prevent agglutination by their own sera. Allow the blood to flow directly into a 16 mm. tube after the first few ml. have escaped into a gauze flat under the hub of the needle. The venipuncture must be accomplished cleanly, and only moderate tourniquet pressure must be used.
2. Cap the tube with Parafilm, invert a few times to ensure adequate mixing of the EDTA and blood, and then centrifuge at 150 g for 20 min. The supernatant platelet-rich plasma constitutes the platelet suspension and should contain 300,000-400,000 platelets/c.mm. on direct count. If the count is higher, a smaller vol. should be employed. If the count is lower but over 100,000/c.mm., the suspension can be used.
3. Obtain sterile test serum by incubating clotted blood in an uncoated test tube for 24 hr. at 37° C. Then separate the serum, using sterile technic, and incubate at 56° C. for 45 min.
4. Add 0.1 ml. EDTA to each 2 ml. serum.
5. Place 0.1 ml. platelet suspension in each 10 × 75 mm. test tube and add 0.4 ml. treated test serum.
6. Shake the tubes to accomplish mixing and place in 5° C. refrigerator for 12 hr.
7. Shake gently and pour ½ their contents into the depressed cell slides.
8. Agitate at 100 rotations/min. for 5 min.
9. Read microscopically at 100×. Wide field oculars facilitate the reading.
10. Platelet clumping is reported as positive or negative.

Laboratory findings in thrombocytopathias (including thrombocytopenia)

Bleeding time: Prolonged.
Tourniquet test (Rumpel-Leede): Positive.
Coagulation time: Prolonged.
Clot retraction: Poor.
Platelet count: Low to normal.
Prothrombin consumption: Abnormal.
Platelet agglutins: May be present.

Thrombotic thrombocytopenic purpura[366, 367]

This is a rather rare febrile disease which pathologically is characterized by arterial and capillary platelet thrombi. The hematologic consequence is severe thrombocytopenic purpura which is accompanied by a hemolytic anemia of unknown etiology. Apart from the purpura and anemia, bizarre neurologic manifestations dominate the clinical picture. The etiology of the disease is not yet known, but some features point to primary vascular disease involving the ground substance. Many of the plugged vessels show deposits of subendothelial fibrin or fibrinoid material. The thrombi contain not only platelets but also fibrin.

The historical review of this disease which is still at times called Moschcowitz's disease is rather interesting. Moschcowitz[368] noted a case which he called "an acute febrile pleiochromic anemia with hyaline thrombosis of the terminal arterioles and capillaries." He called it an undescribed disease although its essential characteristics definitely suggest its similarity to the case of acute hemolytic anemia described by Lederer. In his patient, a 16-year-old girl, the onset was sudden with a rise in temperature, a few petechiae on the arm, and a red blood count of 1,330,000, hemoglobin of 40%, leukocytes 12,600, of which 65% were polymorphonuclear cells. A fragility test showed hemolysis complete at 0.19%. Urine showed albumin and hyaline and granular casts. The patient showed partial paralysis of the left arm and leg and a slight facial paralysis and died 14 days after the onset of the disease. A partial necropsy was done. The heart muscle showed thrombi in the terminal arterioles or capillaries. Vessels were plugged with hyaline masses. These thrombi were first described by Klebs,[369] who noted them in extensive burns. Schmorl[370] found them in the stomach and liver after abrine poisoning. Flexner[371] showed that they arose from agglutinated red cells, proving this by injecting the highly agglutinative substance, ricin, into rabbits.

Epidemic hemorrhagic fever

In June, 1951, United Nations Troops in Korea encountered an acute disease characterized by fever, prostration, vomiting, a variety of hemorrhagic manifestations, shock, proteinuria, and renal failure. A disease known to the Japanese as epidemic hemorrhagic fever and to the Russians as epidemic hemorrhagic nephroso-nephritis or Far Eastern hemorrhagic fever has been described in 2 United States Army Technical Bulletins on Korea and Manchuria.[372, 373]

This disease was first described by the Russians who encountered it in Far Eastern Siberia in the middle 1930's. They found that the incubation period was generally 10-15 days, that a single attack conferred immunity, and that the disease-producing agent would pass through a size N Berkefeld filter. It has been impossible to reproduce this disease in animals. In spite of the failure of animal experiments, it is suggested that hemorrhagic fever may be transmitted to man by rodent ectoparasites, such as fleas, mites, ticks, and chiggers. These chiggers seem best to fit the observed epidemiologic facts.

The complete story on this interesting and new disease is found in the *Symposium on Epidemic Hemorrhagic Fever* by various authors.[374] Briefly, the clinical picture is characterized by sudden onset, in a person recently situated in an endemic area, of chills, fever, prostration, frontal headache, marked thirst, and myalgias. There is a marked facial flush, injection of the palate and conjunctivae, and petechiae of the conjunctivae, palate, axillary folds, and waistline. Proteinuria and reduction in specific gravity of the urine are present.

This clinical course may be divided into 4 phases, each designated by a characteristic physiologic aberration: (1) febrile, (2) hypotensive, (3) oliguric, and (4) diuretic.

In this Symposium, Lt. Robert J. Lukes describes the pathology of 39 fatal cases of this disease. There was almost constant occurrence of hemorrhage in the right atrium of the heart, of severe congestion, hemorrhage, and infarctlike necrosis in the renal medulla, and of hemorrhage and necrosis in the anterior lobe of the pituitary gland, in association with the pattern of the vascular changes. All this supports the contention proposed in the Japanese literature and by Steer and Hullinghorst that capillary damage is the basic process. Retroperitoneal edema, observed only once in secondary shock, is the striking pathologic feature when the patient dies during shock in early phases of the disease. The abrupt increase in incidence of pulmonary edema in the oliguric phase, particularly after the eighth day of the disease when retroperitoneal edema is rare, supports the clinically suspected role of redistribution of fluid and electrolytes with resorption of the abnormal interstitial fluid.

The frequent coexistence of pulmonary edema and bronchopneumonia in the oliguric and diuretic groups and the high incidence of pulmonary abscess formation support the concept of Moon that pulmonary edema of the albuminous type is conducive to the development of pulmonary infections.

The presence of necrosis of the anterior lobe of the pituitary gland in cases suggests that shock is not the only major factor in the pathogenesis of pituitary necrosis in hemorrhagic disease. Anoxemia is also an important factor and is probably the major cause of necrosis in the absence of shock.

Studies of the coagulation mechanism in epidemic hemorrhagic fever reveal abnormalities in prothrombin activity, clotting time, and platelet count. Persistence of thrombocytopenia, which develops early in the disease, through the oliguric-hypertension phase would appear to be causatively related to the bleeding phenomenon observed. Occasional marked deficiencies in plasma coagulation factors are found in seriously ill patients and may contribute to clinically significant bleeding. This plasma coagulation defect is similar to that observed in acute renal insufficiency and has not been clearly defined.

Studies by Giles and Langdon in this report suggest that some mechanism other than decrease in total blood volume is a primary cause of shock in hemorrhagic fever. Although most patients showed normal red cell volumes during the febrile and shock phases of the disease, two showed a significant decrease during severe shock, and many others have decreases in other phases.

Studies by Froeb and McDowell in this report in the *American Journal of Medicine* on renal function in hemorrhagic fever show that the ability to form urine of high specific gravity may persist after the initial decrease in C_{IN} (inulin clearance) and C_{PAH} (*p*-aminohippuric acid clearance) but is subsequently lost. The clearance returns to normal before the concentrating ability.

The following electrolyte abnormalities were observed during the course of hemorrhagic fever. (1) During the oliguric phase, hyponatremia, hyperkalemia, hypocalcemia, and retention of anions were common. However, serious hyperkalemia was rarely encountered, and acidosis was not severe. (2) During diuresis, hyponatremia occasionally resulted from a salt-losing necropathy but more often was due to unknown causes. The hyperkalemia frequently increased during the early diuresis but at this time was not dangerous. Potassium deficiency, associated with the usual symptoms and signs of hypokalemia, sometimes occurred even though hypokalemia was not present. Hunter thus describes electrolyte abnormalities in hemorrhagic fever.

HEMORRHAGIC DIATHESIS DUE TO DEFECTS IN COAGULATION FACTORS

These defects may be hereditary and congenital or acquired.

Afibrinogenemia and hypofibrinogenemia[376-380]

There are 2 types of afibrinogenemia and hypofibrinogenemia—congenital and acquired.

Congenital afibrinogenemia

The rare congenital form of afibrinogenemia is associated with severe hemorrhages that involve the skin and mucous membranes, leading at times to uncontrollable bleeding following relatively minimal trauma (needle stick). The disease is transmitted as a mendelian recessive character and is not sex-linked. It is frequently associated with thrombocytopenia.

Acquired hypofibrinogenemia

Acquired hypofibrinogenemia is seen in liver diseases and maladies involving the reticuloendothelial system. The loss of fibrin can be explained on the basis of intravascular defibrination by the formation of multiple small clots or by the abnormal activation of the fibrinolytic system. Hypofibrinogenemia occurs following operation on the lungs and prostate but is most important clinically as a life-endangering complication of obstetrical conditions such as postpartum hemorrhage, retained secundinae, hemorrhage associated with premature separation of the placenta, and hemorrhage accompanying intrauterine fetal death (dead fetus syndrome). The escape of amniotic fluid, rich in thromboplastin, into the general circulation may lead to the formation of microthrombi in various organs and thus to hypofibrinogenemia. On the other hand, the hypofibrinogenemia may be entirely due to activation of the fibrinolytic system since placenta and uterus contain tissue activators which convert plasminogen (profibrinolysin) to plasmin (fibrinolysin).

Laboratory diagnosis

Screening procedures

If the blood sample in the test tube fails to clot within 6 min. or if an abortive clot forms and lyses rapidly within 1 hr., the presence of hypofibrinogenemia must be suspected. Hemophilia, rare in women, is the only other condition in which blood fails to clot.

Several rapid test methods such as Fibrindex* and Fi-Test† are available commercially.

Quantitative method—estimation of plasma fibrinogen—Goodwin[375]

Principle: Fibrinogen in plasma is precipitated by the addition of sodium sulfite. The precipitate is washed with sodium sulfite and then dissolved in sodium phosphate by heating. Finally, the biuret reaction for proteins is carried out by the addition of a solution of copper sulfate to the dissolved protein. The density of this colored solution is then measured spectrophotometrically.

---

*Ortho Pharmaceutical Co., Raritan, N. J.

†Hyland Laboratories, Los Angeles, Calif.

Reagents:

1. Sodium sulfite, 13%.
    (a) Dissolve 130 gm. sodium sulfite in approximately 800 ml. warm water, transfer to a volumetric flask, and dilute to 1 L.
2. Trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$), 5% aqueous solution.
3. Cupric sulfate ($CuSO_4 \cdot 5H_2O$), 4% aqueous solution.

4. Protein standards. Ideally the protein used for preparation of standards should be human fibrinogen; however, its availability is limited, and as supplied, the salt content of the dried product is not defined so that a weighed amount of this product will contain an undefined amount of fibrinogen. Since this is true, alternative methods of preparing standards will be described; the choice of method should be dictated by the resources of the individual laboratory.
    (a) Fibrinogen standards. Human fibrinogen is available commercially.*
        (1) Stock standard. Dissolve 1.25 gm. fibrinogen in 100 ml. 0.85% sodium chloride. Determine the protein concentration by Kjeldahl analysis† (p. 41) and adjust the concentration to exactly 1 gm./100 ml. by the addition of required vol. 0.85% sodium chloride solution.

Note: In order to convert fibrinogen quantitatively to ammonia it is necessary to use a catalyst and a longer digestion than that required for most serum proteins.

    (b) Albumin standards.
        (1) Stock standard. Prepare a solution of crystalline bovine albumin (available from the same source as fibrinogen) to contain approximately 1 gm./100 ml. Determine the protein concentration by the method used in your laboratory. Adjust the concentration to exactly 1 gm./100 ml. A concentrated solution of human instead of bovine albumin may be diluted if desired.
    (c) Working standards. Dilute 1, 2, 3, 4, 5, 6, 7, and 8 ml. stock standard solution each to a total volume of 10 ml. with 0.85% sodium chloride. These standards are equivalent, respectively, to 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70, and 0.80 gm.% fibrinogen when used as directed in the calibration procedure.

Sample: The sample to be used is plasma obtained from either oxalated or heparinized blood. Hemolysis should be minimized.

Procedure:

1. Pipet 1 ml. plasma into a 12 ml. graduated centrifuge tube.
2. Add 9 ml. 13% sodium sulfite solution, mix thoroughly, and incubate in a water bath at 37° C. for 10 min.
3. Centrifuge at 2500-3000 r.p.m. for 10 min. Pour off the supernatant fluid, drain the tube, and wipe the lip of the tube.
4. Break up the precipitate by blowing in forcibly 5 ml. sodium sulfite solution.
5. Cap the tube and shake vigorously to suspend the precipitate.
6. Wash down the walls of the tube with an additional 3 ml. sodium sulfite.
7. Recentrifuge, pour off the supernatant fluid, and drain the tube.
8. Add 8 ml. sodium triphosphate solution to the precipitate in the tube and heat in a boiling water bath until the precipitate dissolves. This usually requires 10-15 min.
9. Cool the tube and adjust the volume of solution in the tube again to 8 ml. by the addition of distilled water and mix thoroughly.
10. Add 0.2 ml. copper sulfate solution to the tube, stopper, and shake vigorously for 2-3 min.
11. Centrifuge at 2500-3000 r.p.m. for 10 min.
12. Decant the supernatant fluid into a cuvet.
13. Determine the % T of this solution at 560 mμ, using a **blank** composed of a mixture of 8 ml. sodium phosphate solution and 0.2 ml. copper sulfate which has been shaken and centrifuged, as has the unknown.
14. Refer this value to the calibration table to obtain gm.% fibrinogen.

Calibration procedure:

1. Pipet 1 ml. each of the working standards into centrifuge tubes.
2. Add 7 ml. sodium phosphate solution to each tube and mix thoroughly.
3. Add 0.2 ml. copper sulfate solution to each, shake, and centrifuge as for the unknowns.
4. Pour the supernatant solutions into cuvets and determine the transmittance of each as described in the procedure for unknowns.
5. Prepare a concentration-transmittance chart from the values obtained.

Discussion: This method compares favorably with the more tedious methods which make use of thrombin precipitation and gives more reproducible results than those obtained with the turbidimetric procedures.

The volume in which the final color reaction is carried out may be modified to suit the particular photometer used, but when modified, the ratio of the vol. copper sulfate solution to protein solution should always be the same as described here.

Fibrinogen test—Andersch-Gibson modification[381]

Reagents:

1. Sodium chloride solution, 0.9%.
    (a) Dissolve 9 gm. sodium chloride in distilled water and dilute to 1000 ml. with distilled water.
2. Calcium chloride, 0.25%.
    (a) Dissolve 250 mg. calcium chloride in distilled water in a 100 ml. volumetric flask and dilute to 100 ml. with distilled water.
3. Sodium hydroxide, 10%.
    (a) Use 10 gm. NaOH/100 ml. total vol.

---

*Pentex Laboratories, Inc., Kankakee, Ill.

†Fibrinogen contains 16.9% nitrogen.

4. Sodium hydroxide, 20%.
   (a) Use 20 gm. NaOH instead of 10 gm.
5. Standard tyrosin solution.
   (a) Add 250 mg. tyrosin to about 50 ml. N/10 hydrochloric acid in a 100 ml. volumetric flask and dilute to 100 ml. with N/10 HCl.
6. Phenol reagent of Folin and Ciocalteu (p. 46).

Procedure:

1. Place 25 ml. 0.9% sodium chloride solution in a test tube and add 1 ml. plasma.
2. Mix and add 2 ml. 0.25% calcium chloride, placing a small stirring rod in the mixture and allow it to stand for 1 hr.
3. Remove stirring rod containing fibrin and wash with distilled water.

Unknown:

1. Place stirring rod in small tube and add 0.5 ml. 10% sodium hydroxide.
2. Place in boiling water for 30 min.
3. Cool and add 7.5 ml. distilled water.

Standard:

1. Place 2 ml. standard tyrosin solution in a large test tube and add 5.5 ml. distilled water and 0.5 ml. 10% sodium hydroxide.
2. Add to both unknown and standard 1 ml. phenol reagent and 3 ml. 20% sodium hydroxide solution; mix and read in a colorimeter after 30 min.

Calculation:

10/R × 100 × 0.5 mg. × 13 = mg. fibrinogen in 100 ml. plasma.

Range of fibrinogen is 200-400 mg./100 ml. plasma.

Hypoprothrombinemia[382]

There are 2 types of hypoprothrombinemia—congenital and acquired.

Congenital hypoprothrombinemia

Three types of hereditary bleeding diseases exist which have in common a markedly prolonged Quick 1-stage prothrombin time: (1) true hypoprothrombinemia, (2) factor V deficiency, and (3) factor VII deficiency. These diseases are transmitted as nonsex-linked recessive traits.

Acquired hypoprothrombinemia

Acquired hypoprothrombinemia follows vitamin K deficiency, parenchymal liver disease, and therapy with anticoagulants.

1. Vitamin K deficiency. This deficiency is due to difficulty in absorption of vitamin K rather than to inadequate intake. Vitamin K deficiency may be produced by colitis (diarrhea), suppression of coliform bacteria by antibiotics, the abacterial state of the colon of newborn infants, or obstructive jaundice. The various malabsorption syndromes are also included in this classification.
2. Parenchymal liver disease. The inability of the parenchyma of the liver to utilize vitamin K for the production of prothrombin leads to a lowering of the blood level of prothrombin.
3. Therapy with anticoagulants.

Laboratory diagnosis

Prolongation of the Quick 1-stage prothrombin time occurs. If necessary, correction studies can be employed to identify the defect. Stored serum should correct factor VII deficiency. Fresh barium sulfate plasma should correct factor V deficiency, and stored oxalate plasma should correct prothrombin deficiency.

Factor V deficiency

There are 2 types of factor V deficiency: congenital and acquired.

The congenital form as described by Owren[383] is a hemophilia-like disease associated with internal hemorrhage but does not have pronounced joint manifestations.

The acquired form appears in liver disease in conjunction with several other coagulation defects. It has also been described in purpura fulminans and in diseases involving the reticuloendothelial system.

Factor VII deficiency

Factor VII deficiencies may be either congenital or acquired.

The congenital form was described by Owren. Only slight bleeding tendencies are present.

The acquired form is found in all the conditions which lead to defects in prothrombin and factor V.

Hemophilias

Hemophilias are hereditary diseases transmitted as sex-linked recessive characteristics leading to defects which remain the same from generation to generation. Clinically the most constant finding is hemarthrosis, but hemorrhages may occur in many other locations such as the retroperitoneum, pharynx, etc. Certain age periods are particularly dangerous, such as the infant stage (circumcision), the toddler state (dentition and injuries), and puberty. In later life the hemorrhages diminish.

Hemophilia A

Hemophilia A is the classic hemophilia due to a defect in antihemophilic globulin (factor VIII) which may vary from almost complete absence (less than 1%) to a moderate or only slight diminution, leading to various degrees of severity of the disease. The defect lies in the thromboplastin generation and is genetically determined by a gene and its alleles. Hemophilia A is 3-4 times more common than hemophilia B.

Hemophilia B (Christmas disease)

On the basis of the thromboplastin generation test, it is possible to differentiate hemophilia B from the classic type, hemophilia A. Hemophilia B is due to a factor IX deficiency which interferes with the thromboplastin generation and produces a clinical picture which cannot be differentiated from that of hemophilia A. Genetically it is determined by its own gene and does not represent an allelic form of hemophilia A.

Comments: Not too many years ago, most of us had the impression that we fairly well knew the classic disease hemophilia as an entity occurring only in males and transmitted through females as a recessive sex-linked mendelian characteristic. The abnormal bleeding tendency has been known from the early days of the Hebrews who recognized its occurrence after circumcisions, and more recent history has been enlivened by the occurrence of hemophilia in the royal families of Europe. Within medical circles, the abnormally prolonged clotting time of hemophilic blood was well known, and the therapeutic value of blood transfusions was well established.

Any complacency about our knowledge of hemophilia has been fervently shaken by the coagulationists. This has come about chiefly through recent advances in knowledge of the factors involved in blood coagulation. Hemophilia is no longer a simple disease, and there is some question, even in the minds of experts, as to just what the disease is. Dameshek[384] has collected the views of outstanding experts in the field in an attempt to answer this question.[385-393]

As might be expected, there are the same differences of opinion about defining hemophilia as there are concerning nomenclature and theories of blood coagulation. The center of the controversy is the nature of the plasma and platelet factors, excluding calcium, which take part in the conversion of prothrombin to thrombin. A brief glance at the theories of blood coagulation in this area readily reveals many but not all of the differences. We heartily recommend reading this symposium of Dameshek as an enlightening (or perplexing) presentation of how utterly stirred up the concept of hemophilia has become.

Whereas in times past our clinical concern about hemophiliacs was limited to males, we now must consider both male and female bleeders as possible hemophiliacs. Hereditary patterns are being found in the various newly described forms of hemophilia or hemophilia-like diseases as was true of the classic disease. However, acquired defects of clot-promoting factors have been recognized in syndromes simulating hemophilia.

The laboratory diagnosis of hemophilia traditionally rested on a prolonged clotting time. This is no longer true. Although most of the hemophilia-like diseases may have a prolonged clotting time, many instances with a normal coagulation time are being uncovered. Today, in the study of any patient with a bleeding diathesis **not otherwise explained,** one must investigate a plasma defect or defects as possible causes of the disease. There are many tests of varying complexity which can help delineate these defects. Some of these have been elaborated in the section on technic and others will be mentioned here briefly in the following outline:

1. The Quick prothrombin consumption time or the serum prothrombin time. Hemophiliacs show a very short (±10 sec.) time. Hemophilia-like states may show a **shortened** or almost **normal time.** This test is nonspecific insofar as the plasma factors are concerned.
2. Standard prothrombin activity tests, e.g., Quick 1-stage or modifications thereof. These tests show normal times in classic hemophilia but may be abnormal in some of the hemophilia-like diseases.
3. Owren technics for specific factors, such as prothrombin, proconvertin, and proaccelerin. These tests demonstrate specific defects in hemophilia or hemophilia-like disease. It was by the use of such technics that Owren discovered parahemophilia (or factor V) deficiency.
4. The thromboplastin generation test.[394] This test is helpful in distinguishing and assaying various components of the thromboplastin-producing system.
5. The antihemophilic globulin (AHG) assay[280] test measures the specific defect in hemophilia and is useful in detecting latent subclinical cases. Normal AHG assays at 100%, whereas classic hemophilia assays at 0%, moderate hemophilia less than 3%, mild hemophilia 16%, and subhemophilia 33%.
6. The partial thromboplastin test (PTT).

This is a screening procedure in which the plasma of patients with hemophilia and hemophilia-like disease may be brought under scrutiny. The authors[280] have hypothesized the following diagnostic groups: hemophilia, hemophilioid state A, hemophilioid state B, hemophilioid state C, and hemophilioid state D. In all of these the routine PTT gives a prolonged time. However, if equal parts of fresh normal barium sulfate-treated plasma are added to the test plasma, the results aid in differentiation of the states. With such fortified plasmas in hemophilia and hemophilioid state A the partial thromboplastin time returns to normal, but in hemophilioid states B, C, or D the partial thromboplastin time remains prolonged.

Table 244

	Prothrombin time	
	Untreated plasma	*Fortified plasma*
Hemophilia	Normal	Normal
Hemophilioid state A	Prolonged	Normal
Hemophilioid state B	Prolonged	Prolonged
Hemophilioid state C or D	Normal	Normal

These authors have further elaborated their detection and separation system by making standard prothrombin time determinations on untreated plasma and fortified plasma (Table 244).

7. Matching experiments. The basic principle of such tests is determining whether mixing the blood of one individual with that of another corrects a known defect. Such matching experiments originally aided in delineating true hemophilia from some of the subvarieties. It was found that in these subgroups the patient's blood would correct the defect in hemophilia in the same manner as normal blood. Since then, this procedure has become standard practice in the study of hemophilia and related disorders. This technic is limited to separating the entities but does not delineate the specific deficiency. However, an understanding of such matching experiments is helpful in determining therapy. As an example, classic hemophilia will respond to con-

Table 245. *Summary of clinical and clotting characteristics of AHG, PTC, and PTA deficiencies**

	Antihemophilic globulin (AHG) deficiency	*Plasma thromboplastin component (PTC) deficiency*	*Plasma thromboplastin antecedent (PTA) deficiency*
Sex	Male (female very rarely)	Male	Male and female
Hereditary pattern	Sex-linked, recessive trait carried by female and transmitted to male	Similar to AHG deficiency	Not sex-linked; transmitted to male and female by female and probably male carriers
Pattern of hemorrhage:	Depends upon clotting time and the degree of the clotting defect:	Depends upon clotting time and the degree of the clotting defect:	Depends upon clotting time and the degree of the clotting defect:
Degree	Slight to very severe	Slight to moderately severe	Slight to moderate
Sites	Joints frequent, follows trauma and any operative procedure	Joints sometimes involved; follows trauma and operative procedures	Joints rarely involved; most usually follows minor surgical procedures as tonsillectomy, tooth extraction, etc.
Clotting time	Normal to over 1 hr.	Normal to about 60 min.	Normal to 30 min.
Clotting defect corrected by:			
Normal plasma	Yes	Yes	Yes
Normal $BaSO_4$-treated plasma	Yes	No	Yes
Normal serum	No	Yes	Yes
Fraction I	Yes	No	No
Normal $BaSO_4$-treated serum	No	No	Yes
Other findings	Normal values—platelet count, prothrombin time, clot retraction Usually normal—bleeding time, tourniquet test Abnormal (degree related to the extent of the deficiency)—heparin clotting time, serum prothrombin time, recalcified clotting time of slowly and rapidly centrifuged plasma, thromboplastin generation		

*From Rosenthal, R. L.: Am. J. Med. 17:57, 1954.

centrated antihemophilic globulin administration, but other coagulation factor deficiency diseases will not respond favorably.

A typical series of such matching experiments may be found in the paper by Brinkhous et al.[280]

One of the difficulties in matching experiments has been the need for blood from a patient with the deficiency of plasma factor. As the various factors become elaborated, their reproduction in the test tube is becoming more frequent, making such experiments available to more observers. Ideally, the isolation and purification of factors by physical and chemical means would help considerably. Such isolation is understandably difficult when one considers the complexity of the coagulation mechanism.

As a result of studies such as those mentioned have come such names as Christmas disease,[395] parahemophilia,[396] hemophilioid states A, B, C, and D,[280] PTC,[397] plasma thromboplastin antecedent (PTA) deficiency.[398] In addition, there have been designations of various factor deficiencies by number, such as factor V, VI, or VII deficiencies. There is no unanimity of opinion as to which system of nomenclature to adopt, and often there is some question as to whether authors using different terminology are discussing the same syndrome.

Rosenthal[399] presents an enlightening article on the clinical, laboratory, and hereditary patterns of this group of diseases. Table 245 presents an excellent bird's-eye view of plasma factor deficiencies.

Whatever else may be said about these new entities, there is no question that this elaboration has added considerably to knowledge related to the coagulation mechanism.

Laboratory diagnosis of hemophilias

Coagulation time: Prolonged (but results depend on severity of disease).

Bleeding time: Normal.

Prothrombin time: Normal.

Prothrombin utilization: Deficient.

Thromboplastin generation test: Deficient but can be corrected by fresh plasma or blood.

The diagnosis of the hemophilia trait is a difficult one, suggested at times by slight deficiencies in the prothrombin utilization, in prothrombin consumption, and in factor VIII.

PTA deficiency and Hageman defect

These are hemophilia-like (hemophilioid) conditions which are hereditary but autosomal and can affect either males or females. Both represent a defect in the thromboplastin synthesis.

COAGULATION DEFECTS DUE TO CIRCULATING ANTIBODIES

Hyperheparinemia

Hyperheparinemia may be either congenital or acquired.

Congenital hyperheparinemia

Quick described one patient who had no epistaxis, hemarthrosis, or petechiae but bled profusely following injury (delivery). The amount of circulating heparin was sufficient to prevent any thrombin formation.

Acquired hyperheparinemia

Thrombin inhibitors appear in a great variety of conditions such as shock, allergies, collagen disease, thermal and radiation burns, liver diseases, leukemias, and malignant tumors.

Tocantins[400, 401] described an antithromboplastic substance (anticephalin) which in some cases of hemophilia A exceeds in functional activity the antihemophilic globulin which is present in normal quantities.

TRANSFUSION THERAPY OF COAGULATION DEFECTS

Since the laboratory may be responsible for providing the necessary blood factors for a bleeding patient or at least for procuring them, a short list of the defects and their correction by blood or blood fractions follows.

Defect	*Correction factor*
Acute blood loss	Stored blood, fresh blood, plasma, Dextran
Afibrinogenemia	Fresh blood, fibrinogen, lyophilized plasma, stored blood (fresh)
Agammaglobulinemia	Fresh blood, gamma globulin, stored blood
Dicumarol bleeding	Stored blood (fresh), vitamin K_1, fresh blood
Factor V deficiency	Fresh blood, AHG
Factor VII deficiency	Fresh blood, type-specific frozen plasma, lyophilized plasma, stored blood (fresh)
Fibrinolysins	Fresh blood, fibrinogen, lyophilized plasma, stored blood (fresh)
Hemophilia A	AHG, fresh blood, frozen plasma, lyophilized plasma
Hemophilia B	Fresh blood, AHG, frozen plasma, lyophilized plasma
Heparin bleeding	Protamine sulfate

Defect—cont'd	*Correction factor*—cont'd
Hypofibrinogenemia	Fresh blood, fibrinogen, lyophilized plasma, stored blood (fresh)
Hypoprothrombinemia	Fresh blood, stored blood (fresh), lyophilized plasma
Liver diseases	Fresh blood, frozen plasma, albumin
Thrombocytopenia	Platelet concentrates, fresh blood

Chapter 64

The anemias

JOHN D. BAUER

The term anemia is a clinical concept which was used originally to designate a decrease in the total quantity of blood. It is now applied to diseases accompanied by a decrease in the number of erythrocytes or hemoglobin content or both. A clinically important point is that the decrease must be greater than 10% to be of significance. Symptomatically and physiologically, the important factor is the relationship of tissue oxygen needs to the oxygen supplied by the blood.

CLASSIFICATION

There is no one single type of classification that serves all purposes, i.e., diagnosis, prognosis, treatment, and pathophysiology.

Wintrobe[402] grouped the anemias on the basis of the absolute constants of the red cells and hemoglobin.

Classification by mean corpuscular volume (MCV)

- Microcytic anemia—MCV less than $80\mu^3$
  - Etiology
    - Iron deficiency
    - Thalassemia
    - Pyridoxine deficiency
    - Hemoglobin variants
    - Infection
    - Lead poisoning
- Normocytic anemia—MCV equal to $80\text{-}95\mu^3$
  - Etiology
    - Hemolytic anemias
    - Blood loss (up to 3 mo.)
    - Aplastic or hypoplastic anemia
    - Myelophthisic anemia
    - Anemias of pregnancy
    - Anemia of infection
    - Anemia of uremia (kidney diseases)
    - Anemia due to endocrine disturbances
- Macrocytic anemia—MCV greater than $95\mu^3$
  - Etiology
    - Vitamin B_{12} deficiency
    - Folic acid deficiency
    - Anatomical alterations of small intestines
    - Liver disease
    - Hypothyroidism
    - Pregnancy
    - Interference with nucleic acid synthesis (thymine, vitamin C deficiencies, etc.)
    - Hemolytic anemia with early release of marrow reticulocytes
- Diphasic anemia—combination of microcytic and macrocytic

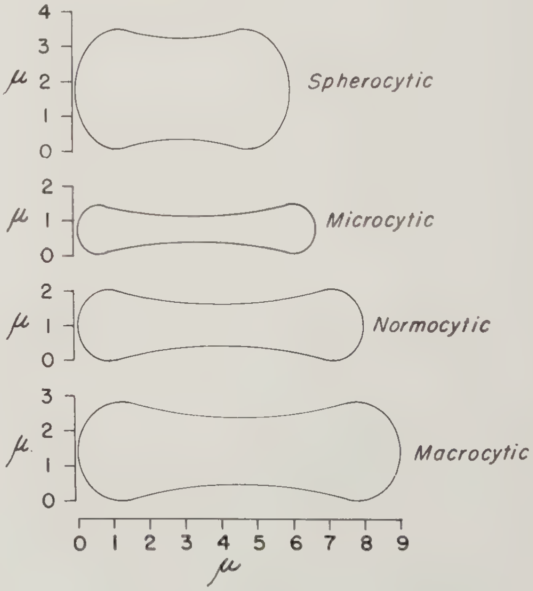

Fig. 405. Schematic representation of side views of various types of red blood cells.

Etiologic classification

This classification presents another approach to the aforementioned morphologic classification based on MCV.

- Interference with red cell production
  - Deficient erythropoietic substances
    - Iron deficiency
    - B_{12} deficiency
    - Folic acid deficiency
    - Pyridoxine deficiency
    - Vitamin C deficiency
    - Magnesium deficiency (?)
    - Thiamine deficiency
    - Orotic acid deficiency
  - Deficient erythropoietin
    - Uremia
    - Infection
    - Endocrine disturbances
  - Marrow replacement
    - Atrophy (drugs)
    - Tumor invasion
    - Fibrous or osseous hyperplasia
  - Dysfunction of marrow
    - Thalassemia
    - Aplastic anemia (interference with release of cells)
- Loss of red blood cells
  - Blood loss (hemorrhage)
  - Hemolysis
    - Intrinsic red cell defects (e.g., spherocytic anemia, hemoglobinopathies, and enzymatic defects)
    - Extrinsic defects (drugs, autoantibodies)
    - Symptomatic hemolytic anemias (lupus, lymphomas, etc.)
    - Hyposplenism

Erythrokinetic classification

Before this classification is given, terminology and methods of investigation of erythrokinetics will be discussed briefly.

Erythrokinetics

This term refers to the quantitative measurement of production and destruction of red cells and their relationship to each other. Normally, production and destruction are in equilibrium. In some anemias this balance is maintained, whereas in others it is lost.

To appreciate erythrokinetics, tests are employed which measure red cell production and red cell destruction.

Terminology:

Total erythropoiesis: Total red cell production irrespective of whether the cells enter the peripheral circulation or not.

Effective erythropoiesis: The cells that enter the circulation and remain there for at least 24 hr.

Ineffective erythropoiesis: The defective cells that remain in the bone marrow and never enter the circulation but are absorbed and destroyed within the marrow.

Methods of investigation of erythrokinetics

Production of red blood cells

Reticulocyte count (measure of effective erythropoiesis): This is considered in the discussion of reticulocytes. These are young red blood cells which have just entered the circulation, are larger than mature red cells, and contain a fine reticulum of ribonucleic acid which disappears in about 24 hr. The reticulocyte response reflects the marrow production of new red blood cells and their release into the circulation. If the reticulocyte response is expressed as percentage of circulating mature cells, 2 factors will determine the percentage: the total number of mature cells and the number of reticulocytes. If the first is decreased, an increase of the latter will result which does not truly reflect bone marrow activity. On the other hand if the reticulocyte count is expressed as reticulocytes/c.mm. whole blood (normal 60,000/c.mm.), the count becomes meaningful and related to erythropoiesis. In megaloblastic anemias in which the erythroid marrow is extremely hyperplastic, the paradox exists that the peripheral reticulocyte count is low, as the marrow reticulocytes shed the reticulum while still within the marrow cavity. In general, a low peripheral reticulocyte count carries a greater degree of inaccuracy than a high count. A low count may therefore be misleading, suggesting an unfounded diagnosis of erythroid hypoplasia or aplasia.

The reticulocyte percentage can also be corrected for changes in the red blood cell volume on the basis of the hematocrit by multiplying the % reticulocyte vol. by % normal of the abnormal hematocrit.

Example:
Reticulocyte value, 25%
Hematocrit, 20 vol.%
Normal hematocrit value, 45 vol.%
Calculation:
$25 \times 20/45 = 11.1\%$ corrected reticulocyte %

The fixed marrow reticulocytes equal the circulating reticulocytes in number. In severe hemolytic processes these young marrow reticulocytes may be released into the peripheral blood and thus produce a rise in the peripheral reticulocyte count which does not actually reflect erythropoiesis. When these young reticulocytes are present, the total reticulocyte count should be divided by 2. The marrow reticulocytes can be differentiated from the more mature forms by their heavy, rich reticulum and nuclear remnants. They fall into group O-1 in Helmeyer's classification of reticulocytes which divides the cells into 4 groups according to the development of the reticulum.

The optimal normal erythropoietic marrow response to blood loss is 6-10 times normal, and in anemia the magnitude of response can be used as an indicator of bone marrow response to treatment.

Red cell utilization of radioiron (measure of effective erythropoiesis): This test includes the plasma iron turnover and the percentage of radioactivity appearing in the circulating red blood cells 2 weeks after injection (normally 75%). This method is particularly useful when the erythropoiesis is depressed and, as already stated, the reticulocyte count is inadequate. On the other hand, the radioiron utilization is inaccurate in hemolytic disease accompanied by marrow erythroid hyperplasia, a condition which can readily be appreciated by the reticulocyte count.

The **normal** is 0.45 mg./100 ml. whole blood/day.

Plasma iron turnover (PIT) (measure of total erythropoiesis): This involves the determination of plasma iron and the rate of disappearance of Fe^{59} citrate from the plasma. This method is not sensitive when erythropoiesis is decreased. It also assumes that the blood volume is normal. The **normal** plasma iron turnover is 0.6 mg./100 ml. blood/day.

Erythroid-myeloid ratio (measure of total erythropoiesis): In normal bone marrow 1 out of every 3-4 nucleated cells is a young erythroid cell. In anemia the ratio of erythroid to myeloid cells in the marrow may increase to 1:1 or even become reversed. This method is inaccurate because it depends on normal leukopoiesis and the absence of any significant dilution of the bone marrow by peripheral blood.

Destruction of red blood cells

Fecal urobilinogen: Since the degraded pigment of hemoglobin is not reutilized, the fecal urobilinogen reflects the amount of hemoglobin broken down per day. This test does not differentiate between the cells destroyed in the bone marrow or in the peripheral blood. External bleeding does not affect the measurement.

Conflicting values obtained by red cell survival studies and fecal urobilinogen may be indicative of excessive ineffective erythropoiesis.

Red cell survival: This test measures accurately the rate of loss of red cells from the circulation, but it does not indicate the pathway of loss, hemorrhage, or hemolysis. One of the best methods is the in vitro tagging of the red cells with Cr^{51} and the reinjection of the tagged cells into the patient. Young cells accept somewhat more radioactive chromium than do older cells. In practice the loss of radioactivity by elution must be taken into consideration.

Anemia-erythrokinetic classification

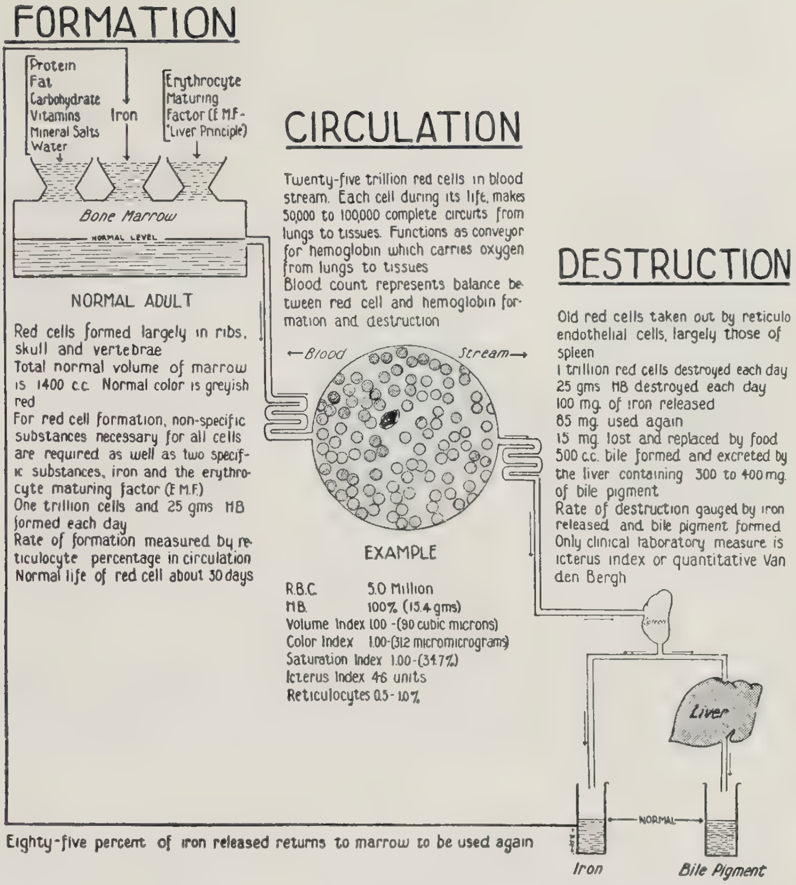
There are two main groups of anemias on this basis: anemias which lack erythroid hyperplasia of the bone marrow (nonproliferative marrow disorders) and anemias which are accompanied by myeloid erythroid proliferation (proliferative marrow disorders).

- Nonproliferative marrow disorders
  - Inadequate marrow stimulation
    - Erythropoietin deficiency
    - Renal disease
    - Endocrinopathies
    - Infection
  - Defective marrow response
    - Marrow damage from drugs, antibodies, and ionizing radiation
    - Marrow exhaustion (form of myeloproliferative disorder)
    - Anatomic replacement of marrow by tumor, fibrous tissue, etc.
- Proliferative marrow disorders
  - Dyspoietic (ineffective) proliferation
    - Abnormal nucleic acid synthesis and metabolism
      - Vitamin B_{12} deficiency
      - Folic acid deficiency
    - Abnormal hemoglobin synthesis
      - Thalassemia
      - Iron deficiency
      - Pyridoxine deficiency
      - Lead intoxication
  - Effective proliferation
    - Loss of blood due to hemorrhage
    - Loss of blood due to hemolysis

Finch, in his discussion of the erythrokinetics in the diagnosis of anemias, states that this approach stresses the site of the defect and points out whether it is premarrow, marrow, or postmarrow.[403]

Figs. 406-419 graphically present the state of the bone marrow, peripheral blood, and related organs with their relative status in normal and various abnormal conditions related to the red blood cells. Study of these illustrations is highly remunerative when related to the discussion in the text.

Text continued on p. 1244.



FORMATION
Protein
Fat

NORMAL
Iron
Bile Pigment

NORMAL ADULT

Red cells formed largely in ribs, skull and vertebrae
Total normal volume of marrow is 1400 c.c. Normal color is greyish red
For red cell formation, non-specific substances necessary for all cells are required as well as two specific substances, iron and the erythrocyte maturing factor (E M.F.)
One trillion cells and 25 gms HB formed each day
Rate of formation measured by reticulocyte percentage in circulation
Normal life of red cell about 30 days

Twenty-five trillion red cells in blood stream. Each cell during its life, makes 50,000 to 100,000 complete circuits from lungs to tissues. Functions as conveyor for hemoglobin which carries oxygen from lungs to tissues
Blood count represents balance between red cell and hemoglobin formation and destruction

EXAMPLE

R.B.C.	5.0 Million
HB.	100% (15.4 gms)
Volume Index	1.00 -(90 cubic microns)
Color Index	1.00-(31.2 micromicrograms)
Saturation Index	1.00-(34.7%)
Icterus Index	4-6 units
Reticulocytes	0.5-1.0%

Old red cells taken out by reticulo endothelial cells, largely those of spleen
1 trillion red cells destroyed each day
25 gms HB destroyed each day
100 mg. of iron released
85 mg. used again
15 mg. lost and replaced by food
500 c.c. bile formed and excreted by the liver containing 300 to 400 mg. of bile pigment
Rate of destruction gauged by iron released and bile pigment formed
Only clinical laboratory measure is icterus index or quantitative Van den Bergh

Eighty-five percent of iron released returns to marrow to be used again

Fig. 406. Normal red cell physiology. The cells are being formed and destroyed at a constant rate. The cells vary little in volume and hemoglobin content. Rate of delivery of new cells is gauged by the reticulocyte count and the rate of destruction by the icterus index. Blood count and hemoglobin content show only the balance between formation and destruction of red cells. *Editor's note:* Normal life of the red blood cells is 120 days instead of 30 days. (From Haden, R. L.: J. Lab. & Clin. Med. **22**:439, 1937.)

Fig. 419. Red cells in polycythemia vera. In this disease there is an enormous overproduction of erythrocytes and the marrow is filled with erythrogenic tissue. Rate of destruction does not keep pace with red cell formation and the blood volume increases. Increase in red cells per unit volume and in blood volume gives a great increase in red cell mass. (From Haden: R. L.: Principles of hematology, Philadelphia, Lea & Febiger.)

MICROCYTIC ANEMIAS

Iron-deficiency anemia (sideropenia)

The most common type of anemia is iron-deficiency anemia. The well-established anemia is hypochromic microcytic and shows some anisocytosis and poikilocytosis.

This anemia is closely linked to iron metabolism (ferrokinetics), and therefore this aspect is discussed briefly first.

Iron metabolism

In the normal adult (70 kg.) there are about 4-5 gm. iron which have the following distribution: hemoglobin 65-75%, storage depots (liver, spleen, and bone marrow) 15-25%, myoglobin 5%, and enzymes (cytochromes, catalase, etc.), 5%. Alimentary iron is absorbed mainly in the duodenum, some in the jejunum, and hardly any in the stomach, ileum, and colon. In the stomach alimentary iron is broken down to ionized ferric iron (Fe^{+++}) which is then reduced to ferrous iron (Fe^{++}) by ascorbic acid, cysteine, and the sulfhydryl groups of food proteins. Although Moore and others have shown that hydrochloric acid is not essential for ionizing alimentary iron, many European investigators believe that achlorhydria interferes with effective iron absorption. About 5-10% of the alimentary iron is absorbed. If the diet contains 12-15 mg. iron/day, 0.6-1.5 mg. will be absorbed. The mechanism and the control of iron absorption are not clear. There are many good arguments against Granick's mucosal block theory which postulates that the intracellular concentration of ferritin within the duodenal mucosa regulates the iron absorption. In diseases characterized by high serum iron the iron absorption continues at the normal rate. Saltman showed that the iron transfer may be in part a chelating process depending (1) on the total number of available binding sites of ferritin or transferrin, (2) on the stability of each of these sites, and (3) on the competition of other ions for these sites. The iron absorption depends on several factors. Iron in various foods is not equally well absorbed. Iron deficiency and marrow erythropoietic hyperplasia increase the amount of absorbed iron several times (20%), whereas marrow erythropoietic hypoplasia and large iron deposits in the storage organs tend to retard iron absorption. It is further delayed by increased intestinal motility and by diets con-

taining large amounts of certain organic acids such as lactic acid.

In the process of absorption the ferrous iron is oxidized to the ferric state and is bound to an α-2 globulin, apoferritin, the iron complex of which is called ferritin. Apoferritin is rapidly synthesized and is equally rapidly broken down in the mucosal epithelial cells. The ferric form is again reduced to the ferrous form and diffuses into the plasma where it circulates as Fe^{+++} bound to a β globulin, transferrin or siderophilin. This protein is normally only one third saturated with iron. Iron is thus transported to the storage depots—bone marrow, liver, spleen—but it is mainly utilized for hemoglobin synthesis. Small amounts are incorporated into enzymes and myoglobin. In hemoglobin the iron is present in a mineralized form.

The body carefully conserves iron by reutilizing iron which is liberated in the process of cellular catabolism (especially hemoglobin iron). Iron is stored as ferritin which contains iron as $Fe(OH)_3$ and does not stain with Prussian blue dye. Excess iron is stored as hemosiderin which is a protein, containing nucleotides and iron as iron hydroxide gel. Hemosiderin stains blue with Prussian blue. Hemosiderin may play some role in the cellular defense mechanism. This process is reversible so that iron can be transferred from siderophilin to ferritin and hemosiderin and vice versa. Iron deficiency does not therefore occur until all 3 proteins are depleted of iron.

Most of the alimentary iron is excreted in feces. A small amount of iron is lost in urine, sweat, and cutaneous and intestinal desquamating cells. Parenterally administered iron is not excreted. Blood loss from any source, whether physiologic such as menstruation or pathologic such as hemorrhage, adds to the iron loss. The average daily loss for adult men and postmenopausal women is 0.5-1 mg. iron. In menstruating women the loss increases to 1-1.5 mg. These figures roughly represent the daily minimal iron requirements of these 3 groups. During pregnancy and delivery the iron loss of a mother is in the neighborhood of 100-500 mg. In childhood during the growth periods, 0.6 mg. of iron must be absorbed daily in excess of the normal requirements.

The **erythrokinetic data** in a normal man (70 kg.) are as follows: blood volume, 5000 ml.; red cell mass, 2000 ml.; daily turnover of red cells, 16.7-20 ml. These figures correspond to a hemoglobin mass of 666 gm. and a daily hemoglobin turnover of 5.6-6.7 gm., which in turn corresponds to a circulating iron mass of 2254 mg. and a daily iron turnover of 18.5-22.5 mg. The depot iron amounts to about 1000-1500 mg.

The investigation of human ferrokinetics is made possible by the administration of radioiron (Fe^{59}) which allows measurement of (1) radioiron utilization for hemoglobin formation, (2) of plasma volume (in conjunction with P^{32} of red cell volume), and (3) determination of circulating iron and iron storage and excretion.

Laboratory findings

Hematologic findings

Peripheral blood:

RBC: decreased (3-4 million/c.mm.).

Hemoglobin: decreased (6-10 gm./100 ml.).

Constants

MCV less than 80 μ^3.

MCH less than 27 $\mu\mu$g.

MCHC less than 32%.

Blood films: Hypochromasia, microcytosis, planocytosis, anulocytosis, occasional target cells, and anisocytosis.

Reticulocytes: Usually decreased; most are young.

Osmotic fragility: Normal to decreased (presence of target cells).

White blood cell count: Normal; often slight leukopenia with lymphocytosis; granulocytes may be hypersegmented and small.

Platelets: Normal; sometimes slightly diminished.

Serum iron: Low, less than 60 μg/100 ml. blood; total serum binding capacity high, greater than 350 μg/100 ml.; rapid response to parenteral iron administration.

A single serum iron determination is to be interpreted with caution because of the great normal variations of serum iron. Radioiron shows rapid absorption, rapid removal from plasma associated with rapid uptake by the bone marrow, and slight shortening of the life span of red cells. There is minimal radioiron excretion.

The diagnosis of depleted iron stores can be made by the iron absorption test. After an iron test dose of about 170 mg. Fe, a rise of serum iron over 280 mg.% after 2 hr. is indicative of iron deficiency.

Bone marrow: Increase in basophilic normoblasts which may show nuclear cytoplasmic dissociation due to nuclear condensation

preceding cytoplasmic hemoglobinization. The cytoplasm appears to be mechanically weak so that the edges are irregular, and often naked nuclei appear (ineffective erythropoiesis). In the storage organs, including the bone marrow, hemosiderin is absent. The absence of bone marrow hemosiderin is an important finding in iron deficiency. Because iron returns slowly into the depleted storage depots, the absence of bone marrow hemosiderin is a diagnostic finding in latent sideropenia[404] (masked iron deficiency) in which case the patient suffers from iron-deficiency anemia, but the serum iron and the hemoglobin values are only slightly depressed.

Nonhematologic findings

Frequently gastric achylia is found which is occasionally histamine fast. There may be atrophy of the epithelial cells of the gastrointestinal tract (cytochrome deficiency?), and oral epithelial cornification has been described. Rarely bone changes can be seen on radiologic examination.

Causes of iron-deficiency anemia

Following is a list of the main causes of iron deficiency.

1. Insufficient intake, which includes poor dietary habits, inadequate diet during childhood, and reducing diets.
2. Inadequate absorption, which includes achlorhydria (?), extensive gastric resection, substances interfering with absorption such as citric acid and lactic acid, lack of ascorbic acid, accelerated passage as in chronic diarrhea, and colitis.
3. Increased demand, which occurs during pregnancy, in growing children, and from blood loss and blood regeneration.
4. Blood loss, which includes physiologic loss during menses, and pathologic as from hemorrhage and hemolysis.
5. Abnormal intrinsic iron metabolism, which occurs in pulmonary hemosiderosis and sideroachrestic anemia.

Insufficient intake

Except in extreme cases of general malnutrition or malabsorption, insufficient intake is not the cause of iron deficiency in adults.

Iron deficiency in infants and children: In infants and children iron deficiency is a common cause of anemia. Physiologically, from birth on the hemoglobin and number of red blood cells fall rapidly up to 3 mo. so that the storage depots become filled with iron from the breakdown of red blood cells. From 3 mo. on the depots become gradually depleted if the infant is on a pure milk diet, as milk alone does not supply enough iron to restore the depot iron. This physiologic(?) iron deficiency is even more marked if the child is premature or is one of twins, if the placental blood was not allowed to drain into the infant at the time of birth (cesarean section), or if the infant bled into the maternal circulation[405] or was born after placental hemorrhage had occurred. Iron-deficiency anemia is common at the end of the first or second year, after which time the iron storage depots are slowly replenished.

Chlorosis

Chlorosis is of historic interest only. The name refers to a form of perhaps hereditary iron-deficiency anemia often accompanied by achlorhydria which had its peak in 1890, 1900, and 1901 in Europe and has since disappeared. The cause of its disappearance is unknown and is perhaps related to dietary and social habits. Heilmeyer made the remark that many families' recipes are also hereditary.

Chlorosis is a very interesting disease frequently seen in young women although Castle and Minot[406] state: "At present it is very rarely observed at least in the form described in the medical literature of the preceding three centuries. Undoubtedly cases of hypochromic anemia in young women, recognized today as associated with defective diets, decreased gastric secretions, and chronic blood loss, would have been called chlorosis a generation ago."* They exhibit symptoms of weakness. These patients will complain in the morning after a good night's sleep of not being refreshed by sleep, but in the afternoon and toward the evening this weakened condition disappears. They are not necessarily pale. They complain of a tired feeling, headache, difficulty in breathing after bodily exercise, palpitation of the heart, pain in the side, and disturbances of menstruation. Dyspeptic symptoms are frequent.

They are often pale but not necessarily so. The lips and visible mucosae are pale, but the cheeks are not. The skin color may be pale yellow or pale green.

Clinical symptoms are as just described, plus dark spots floating before the eyes, disturbances in accommodation, and quick fatigue after reading. The retina is pale and is characterized by transparency of the blood vessels. There may be spasms with cold hands and feet. Thromboses have been described in this disease. The pulse is full, soft, and dicrotic. Blood pressure is normal. The spleen is not necessarily enlarged, according to Schilling, although von Noorden states that it is always enlarged.

Blood loss

Hemorrhagic and posthemorrhagic anemia: Certain changes in the blood picture are of importance in estimating the extent of the hemorrhage and the amount of attempted regeneration on the part of the erythropoietic and leukopoietic systems.

A rapidly rising erythrocyte count, i.e., a constant rise if counts are taken hourly or periodically during the day, denotes a possible hemoconcentration leading to shock.

---

*From Castle, W. B., and Minot, G. R.: Pathological physiology and clinical description of the anemias, New York, 1936, Oxford University Press.

Leukocytosis with neutrophilia and no shift is seen following hemorrhages. In severe hemorrhage there is a slight left shift. In exhausting hemorrhages there is a regenerative shift.

Marked polychromasia in the blood film (rise in reticulocytes) indicates regeneration of the erythrocytes and is a good sign following a hemorrhage. Basophilic punctation means degenerative effects, possibly toxic, on the erythrocytes. An occasional normoblast can be found in the blood in severe hemorrhages as a sign of rapid regeneration of the erythrocytes, but if many normoblasts appear, there is overstimulation of the erythropoietic system, and this is regarded unfavorably.

Blood platelets rise rapidly following a hemorrhage.

Roughly 50 mg. Fe are lost per 100 ml. blood. The hemorrhage may be intermittent and may be so small in amount as to be difficult to detect and may come from hidden lesions which may be difficult to diagnose such as diverticula, hiatus hernia, etc. Excessive menstrual loss, frequent pregnancies, and frequent blood donations to blood banks all may account for iron loss.

In general the blood count immediately following hemorrhage will not reflect the blood loss. As the organism attempts to compensate for the blood loss by mobilizing interstitial fluid, which is poor in protein, the blood count and the serum protein will fall. This fall may continue for several days even though the hemorrhage has ceased. The normal iron depots contain about 1000 mg. iron, which is enough to compensate for the loss of 1 or 2 L. blood by mobilizing 20-40 mg. a day. If the blood loss is sudden and of any magnitude, young marrow reticulocytes together with nucleated cells are released into the circulation. Bone marrow erythroid hyperplasia will follow within a matter of hours and days. If the blood loss continues, the erythropoiesis will extend into fatty marrow, replace it, and expand the marrow-containing spaces. Potentially erythropoietic organs such as the spleen, liver, lymph nodes, and retroperitoneal fat (extramedullary metaplastic erythropoiesis or hematopoiesis) are called into play.

Hookworm anemia

The anemia is a typical iron-deficiency anemia, related to the severity of the infection, the nutritional state of the patient, and the coexisting iron (blood) losses, such as menses. It is reported that each worm consumes 0.67 gm. hemoglobin daily. Additional factors are the nutritional hypoproteinemia and the malabsorption related to the hyperperistalsis of the diarrhea.

Hookworm anemia has been known since the construction of the Gotthard tunnel in Switzerland in the years 1876-1880. Perroncito[407] noted that many Italian workers developed a severe and at times fatal anemia, with hookworm infestation. Later, hookworm anemia was called miner's anemia because of its occurrence in mines. Boycott[408] described cases of hookworm anemia in England (1901). Later hookworm anemia was observed in other European countries, in America, and in tropical countries where suitable conditions for hookworm infestation exist.

The etiology of this disease has been well discussed in many papers. Stransky and Quintos[409] gave an accurate description of it from their experience in the Philippines, where the Ancylostoma is very common.

They observed 3 types or stages of blood changes in hookworm disease. In the first type the bone marrow is able to maintain the equilibrium between blood loss and production, and there is no manifest anemia. They call this the stage of compensated anemia. In the second type the production is unable to counterbalance the blood loss, and a hypochromic anemia results. In the third type the bone marrow is exhausted, and aplastic anemia develops. In the first type they found in the peripheral blood eosinophilia and reticulocytosis without anemia. The bone marrow findings were characterized by increased erythropoietic activity and likewise eosinophilia. Despite a continuous loss of blood, an increased production in the bone marrow was sufficient to maintain the equilibrium between blood formation and blood loss. In the early stage of hookworm disease, real anemia may not develop if food and living conditions are adequate.

In the second type, they described these characteristics—anemia, microcytosis, hypochromia, eosinophilia, and reticulocytosis in the peripheral blood, and eosinophilia and marked erythropoietic activity of the bone marrow.

Hookworm anemia is hypochromic and microcytic, with a red cell count of 1-3.5 millions/c.mm. In advanced cases the red cell count may drop to below 1 million. Eosinophilia usually amounts to 5-15% although in more advanced cases eosinophilia may no longer be present. In some cases there may be a hypoplastic tendency of the bone marrow, but the condition is still reversible and the patient recovers.

The third type or irreversible type (aplastic anemia) is characterized clinically by severe anemia, dizziness, easy fatigability, and hemorrhagic diathesis. The erythropoietic activity of the bone marrow is almost nil. There is so-called panmyelophthisis with low cell count, relative lymphocytosis, and lack of erythropoietic, granulocytopoietic, and thrombocytopoietic activity of the bone marrow. In this stage antihelminthic and antianemic treatments are of no avail. Blood transfusions and iron are ineffective in improving the irreversible process. Aplastic anemia as a possible outcome of hookworm infestation has only rarely been mentioned. Stransky and Quintos observed 8 cases of aplastic anemia in hookworm disease. In one case there were hypochromia, anemia, leukopenia with granulocytopenia, relative lymphocytosis, thrombocytopenia, and reticulocytopenia in the peripheral blood. There were low cell count, relative lymphocytosis, poor erythropoietic activity, and megakaryocytopenia in the bone marrow. In 2 other cases although the outcome was the same as aplastic anemia, the hematologic picture at first was not definitely that of panmyelophthisis. One of these cases was an example of severe anemia with symptoms of early hemorrhagic diathesis. From the hematologic picture alone, the diagnosis of aplastic anemia could not be definitely made during the stay of the patient in the hospital for 7 weeks. However the outcome was fatal, and in 2 weeks after discharge, there was probably a rapid breakdown of the bone marrow. In another case, anemia was not extreme at first, with a count above 1 million, the bone marrow count was 105,000, which is about normal, and the differential count was not much altered, but the erythropoietic activity of the bone marrow was low, the ratio of nucleated red cells to white cells was 0.19:1.0 compared with 0.3:1.0; 0.6:1.0; and 1.1:1.0 in those that recovered in the second type. The hematologic symptoms, leukopenia with relative lymphocytosis, thrombocytopenia, low reticulocyte count, and absence of nucleated red cells in spite of the anemia shown by the peripheral blood, were in favor of aplastic anemia even in the beginning of the observation, despite the somewhat normal bone marrow findings. These authors believed that their cases of aplastic anemia were not simply coincidental with hookworm anemia but were actually related to it. They believed that the aplastic anemia of hookworm disease is due to bone marrow exhaustion following continuous blood loss in the presence of various factors, including dietary deficiency.

Pathophysiology of iron-deficiency anemia

The first response to iron loss is depletion of the iron stores, followed by an increase in plasma transferrin. The increase may represent an attempt to augment iron absorption. As this fails to take place, the serum iron falls so that an anemia is produced which at first is normocytic normochromic, but as the iron deficiency continues, it becomes microcytic hypochromic.

Differential diagnosis of iron-deficiency anemia

Anemias due to trace element deficiencies

The 2 trace elements of concern are cobalt and copper.

Cobalt: In man a diet devoid of cobalt should lead to the development of pernicious anemia since cobalt is a constituent of vitamin B_{12}. The completely cobalt-free diet is not feasible because of the ubiquity of cobalt. In animals cobalt deficiency diseases are well recognized and are frequently accompanied by microcytic anemia. In animal and man the administration of cobalt stimulates erythropoiesis and hemoglobin formation, probably by producing cellular anoxemia by interference with oxygen utilization through blocking of oxidation enzyme systems. Enzymatic blocking also accounts for the goiterogenic effect of high doses of cobalt.

Copper: Copper is a constituent of many essential enzymes, and together with iron it is necessary for the synthesis of hemoglobin. Milk is poor in copper so that a pure milk diet will lead to copper deficiency which is usually accompanied by a microcytic anemia. The hematologic action of copper may be linked to its effect on iron metabolism as it supports iron absorption and transfer. Red blood cells contain a copper-containing protein, erythrocuprein. The copper contents of red blood cells is in the range of the serum copper level, 93-114 mg./100 ml. The serum copper level may fluctuate, whereas the red blood cell copper level is usually constant. Copper is stored in the liver (higher in fetal liver), bones, and nerve tissue. Most of the serum copper is bound to an α-globulin, ceruloplasmin. Normal plasma contains 30 mg. ceruloplasmin/100 ml. A small amount of serum copper is loosely bound to albumin and is called direct reacting copper. It probably represents copper in transport. Plasma copper is elevated in liver diseases, pregnancy, tumors and schizophrenia and is decreased in hypothyroidism and nephrosis. In Wilson's disease, a form of hereditary deficiency of ceruloplasmin, the total serum copper level is normal or only slightly decreased because the direct acting copper is unusually high and thus makes up for the deficiency of ceruloplasmin.

Screening test for plasma ceruloplasmin[409a]

This method is based on the fact that ceruloplasmin catalyzes the oxidation of paraphenylenediamine, the rate of oxidation being proportional to the plasma concentration of ceruloplasmin. The oxidation results in a purple-blue compound. Prepared paper strips, etc., are available commercially.*

Anemia of infection

At first the anemia is usually normochromic normocytic in type, but after longer duration it becomes hypochromic. The serum iron level is low, as it is in true iron deficiency anemia, but the serum iron binding capacity is diminished, whereas in true iron-deficiency anemia it is increased. The serum copper is elevated (150-250 μg%), whereas in iron-deficiency anemia the serum copper is normal or only slightly elevated (130-150 μg%). The anemia responds poorly to oral or parenteral iron, and the iron tolerance test fails to raise the serum iron level, whereas in iron-deficiency anemia it is raised within a period of 2 hr. Korman[410] describes a differential test using intravenous radioiron containing 0.6 mg. carrier iron chelated with sodium ethylenediamine diortho hydroxyphenyl acetate (EDDHA) which allows differentiation of iron-deficiency anemia and the anemia of infection, renal disease, and depressed erythropoiesis.

The cause of the hypochromic anemia of infection is not clear. Heilmeyer[411] believes that the anemia is related, first, to a disturbance of the hemoglobin synthesis based on the dysproteinemia, and, second, to the activity of the reticuloendothelial system which mobilizes iron and deposits hemosiderin in the area of infection, thus increasing the tissue iron. There may also be an increase in the iron-containing enzymes so that the iron deposition can be considered a nonspecific defense mechanism. It should be recalled that anti-infectious properties have also been ascribed to transferrin. Radioiron studies show lowering and rapid transfer and turnover of the plasma iron as well as poor utilization of iron from hemoglobin synthesis. The red blood cell survival time is also shortened. The elevated serum iron level in acute hepatitis is an important exception to the phenomenon just described and constitutes a diagnostic test for this disease.

Sideroachrestic hypochromic anemias of Heilmeyer[412]

These anemias are due to interference with hemoglobin synthesis so that iron, though present in adequate amount, cannot be utilized. The serum iron level is high, and administration of iron fails to cure the anemia. The iron stores are loaded with iron (hemosiderin), and siderocytes and sideroblasts appear in bone marrow and blood.

Classification

- Essential hypochromic sideroachrestic anemia
  - Hereditary hypochromic sideroachrestic anemia
  - Refractory sideroblastic anemia (same as Dacie's refractory normoblastic anemia)
- Secondary sideroachrestic anemia
  - Anemia due to infection
  - Toxic anemia (lead)
  - Vitamin-deficiency anemia, pyridoxine deficiency
  - Thalassemia

Both essential hypochromic sideroachrestic anemias are due to enzymatic defects in the porphyrin metabolism. In the hereditary form there is a lack of enzymes which catalyze the conversion of coproporphyrin to protoporphyrin. In the acquired form there is a similar defect, but at the same time there is a defect in the enzyme which incorporates iron into the protoporphyrin ring.

In the secondary anemias the defect in iron utilization is only one aspect of a primary disease.

Pyridoxine (vitamin B_6)-deficiency anemia[413-415]

Pyridoxine-deficiency anemia is a hypochromic anemia characterized by high serum iron and high iron level in storage depots (hemosiderosis); it is refractive to treatment with Fe but responds to pyridoxine. The diagnosis can be made by the tryptophan tolerance test and by the response to treatment with pyridoxine. The tryptophan tolerance test consists of the estimation of xanthuric acid in the urine after an oral test dose of tryptophan.

---

*Ortho Pharmaceutical Corp., Raritan, N. J.

Normally, tryptophan is converted to 3-oxykynurenin which gives rise to nicotinic acid with the help of intermediary compounds, enzymes, and vitamin B_6. If this pathway is blocked, oxytrynurenin gives rise to xanthuric acid. In vitamin B_6 deficiency under the conditions of the test, the xanthuric acid excretion is increased (normal, 50 mg.). Pyridoxine hydrochloride is utilized to form pyridoxal phosphate, a coenzyme involved in the synthesis of heme. Pyridoxine deficiency has been found in patients with malignant tumors, in children on a pyridoxine-deficient diet, in pregnant women, and in patients under treatment with isoniazid, a pyridoxine antagonist.

Thalassemia

Thalassemia is characterized by increased serum iron, presence of fetal hemoglobin, increased amount of hemoglobin-A_2, presence of target cells, basophilic stippling, nucleated red blood cells, hepatosplenomegaly, characteristic fascies, skeletal changes, and evidence of hemolysis. This disease is considered in the discussion of hemoglobinopathies.

MACROCYTIC ANEMIAS

There are 2 factors that must be considered in the discussion of pernicious anemia and related macrocytic anemias, namely, the intrinsic and the extrinsic antianemia factors. The intrinsic factor is an indefinite something which is neither hydrochloric acid, rennin, pepsin, nor lipase. It is deficient in pernicious anemia. It is found in the gastric secretion in other types of anemia, including aplastic anemia and chronic hypochromic anemia. The extrinsic factor, is present in beef muscle and in many other foods. It is not ether soluble, it passes through an ultrafilter, and it has been identified as vitamin B_{12} or cyanocobalamine, which chemically with its central cobalt surrounded by pyrrol rings somewhat resembles porphyrins. Macrocytic anemia occurs by reason of the lack of extrinsic factor in the diet or through a combination of dietary deficiency, insufficient intrinsic factor, or faulty absorption.

CLASSIFICATION

- Hereditary constitutional megaloblastic anemia
  - Pernicious anemia (absence of intrinsic factor)
- Symptomatic megaloblastic anemia
  - Malabsorption syndromes, vitamin B_{12} and folic acid deficiencies
    - Primary
      - Tropical sprue
      - Idiopathic steatorrhea
      - Celiac disease
    - Secondary
      - Regional ileitis
      - Small intestine resection
      - Blind loop operation
      - Chronic pancreatitis
      - Diverticula
      - Stomach resection
      - Gastric carcinoma
      - Hypothyroidism
  - Nutritional anemia, diminished supply of folic acid or vitamin B_{12}
    - Kwashiorkor
    - Goat milk anemia
    - Inadequate diet
  - Increased utilization of folic acid and vitamin B_{12}
    - Anemia of pregnancy
    - Anemia of infancy
    - Fish tapeworm *(Diphyllobothrium latum)* infestation
    - Pathologic intestinal flora in blind loop operations
    - Strictures of small bowel
    - Diverticula
    - Leukemia
  - Accompanying liver disease
  - Following administration of drugs
    - Anticonvulsants—Dilantin, primidone, amytal, Seconal, Rutonal, folic acid antagonists

HEREDITARY CONSTITUTIONAL MEGALOBLASTIC ANEMIA

Pernicious anemia

Pernicious anemia is known also as Biermer's disease or more properly morbus hunteraddisonii. It is clinically a symptom complex of a severe megalocytic anemia accompanied by marked intestinal symptoms, glossitis, achylia, dyspepsia and nervous symptoms, paresthesias, some cases showing the characteristic subacute combined degeneration of the cord and various psychic changes in the individual.

This disease was formerly always considered fatal: once the diagnosis was made, the death warrant was practically signed, but with the discovery of liver therapy by Whipple, Minot, and Murphy and the therapy of hogs' stomach by Castle, this disease has largely lost its terrors; its victims have been practically recalled from death to life.

Etiology

Pernicious anemia, as well as related macrocytic anemias, has been classified by Castle and Minot[406] as insufficient blood production due to nutritional deficiency of the bone marrow. Almost every type of macrocytic anemia showed prompt response to the administration of extracts of liver. If this liver therapy is discontinued, relapses occur. This seems to eliminate the former theories of infections, toxins, and noxae to explain the etiology of anemia of the macrocytic type. It was discovered in 1926 by Minot and Murphy[416] that liver therapy was effective in the treatment of pernicious anemia. This seemed to emphasize the deficiency theory of pernicious anemia. Minot, Murphy, and Stetson[417] proved that the reticulocyte response to the feeding of liver was a proof of the effectiveness of the agent. Castle[418] and others showed that untreated patients with pernicious anemia were deficient in gastric secretion of an essential thermolabile constituent or intrinsic factor. It was shown by Castle and Townsend[419] that the gastric secretion of the normal individual was ineffective by itself. Similarly, beef muscle was also ineffective on administration to suitable patients with pernicious anemia. The beef muscle, called the extrinsic factor, when combined with the normal gastric secretion, increased blood production and clinical improvement similar to that induced by liver therapy.

Pernicious anemia, therefore, develops in individuals whose gastric juice contains insufficient amounts or none of the intrinsic factor to react effectively with the food. Expressed in other terms, normal gastric juice with food produces the active principle which is stored in the liver, kidney, and other tissues of normal individuals and permits normal bone marrow function to go on and thereby prevents anemia. Castle and associates believe that pernicious anemia develops from a lack of the intrinsic or extrinsic factor or a little of each. They also believe that defects of intestinal absorption, even with a normal gastric mechanism, may lead to pernicious anemia. Sturgis and Isaacs[420] showed that pig stomach was effective in the treatment of pernicious anemia, and therefore, this organ had the same substance present as normal gastric juice of man. The liver substance or factor that helps the bone marrow to return to normal in cases of pernicious anemia is able to resist boiling, while that in normal human gastric juice and in pig stomach is rapidly destroyed by temperatures above 70° C. Meulengracht[421] proved that the factor is present in the pyloric region of the pig stomach.

The isolation of vitamin B_{12} and related cobaltamines appears to have solved the problem of extrinsic factor, with which it has come to be identified. Jukes[422] has summarized the biochemistry of folic acid and vitamin B_{12}. Vitamin B_{12} has a molecular weight of 1550-1750 and contains cobalt which accounts for its red color. It is effective in microscopic quantities in producing a remission in patients with pernicious anemia when given parenterally. Oral administration is ineffective unless administered simultaneously with or shortly after ingestion of intrinsic factor. If large doses of cyanocobalamine are administered by mouth, a small percentage is absorbed by diffusion without the help of the intrinsic factor.[424] A daily dose of 1000 μg will maintain normal concentration of cyanocobalamine in the serum.

Rubbo[423] presents the present-day concept of the enzyme systems involved in red blood cell production. He visualizes the action of folic (folinic) acid as catalyzing the pyrimidines from methionine. The second stage involves vitamin B_{12} as the catalyst for a combination of the pyrimidines and ribose (or desoxyribose) to form thymidine (nucleosides). Although a considerable amount of work has been done on vitamin B_{12}, showing its relation to nucleoprotein synthesis, there still remain many gaps in our knowledge of this complex mechanism. Assay of vitamin B_{12} activity has been carried on by determination of growths of *Lactobacillus leishmanii, Escherichia coli* mutants, *Euglena gracilis,*[425] and *Pateriochromonas stipitata.*

The mean normal serum value is about 350 $\mu\mu$g/ml. In pernicious anemia the value falls to 38 $\mu\mu$g/ml. In chronic myelogenous, leukemia, polycythemia, and in liver disease, high values are found, while in lymphatic leukemia and in pregnancy the values are normal or low. Microorganisms are able to synthesize B_{12}, and herbivorous animals are able to utilize vitamin B_{12} produced by intestinal bacteria. Man is unable to do so and has to rely on animal meat as source of vitamin B_{12}. Plants contain very little if any vitamin B_{12}, whereas liver, milk, cheese, fish, and molasses are rich in this vitamin. Vitamin B_{12} in food must be absorbed, and this is accomplished either with the help of intrinsic factor or by diffusion. In serum, vitamin B_{12} is bound to α-globulin.

Glass and associates,[426] using *Euglena gracilis* for assay, found oral administration of vitamin B_{12} together with a potent intrinsic factor concentrate caused a sharp rise in vitamin B_{12} blood level, but less than 0.5% in the urine. A rise in urinary output of vitamin B_{12} occurred after the reticulocyte peak.

Vitamin B_{12} has been linked with various isotopes for experimental studies which have yielded a considerable store of information, most of which has been directed at determining mechanisms involved in the interaction of the various factors involved in macrocytic anemias. Tests based on the low urinary output of orally ingested radioactive vitamin B_{12} have been used to detect pernicious anemia patients in remission.[427]

The attack on the nature of intrinsic factor continues unabated and the elusiveness of this factor continues to interest and baffle investigators. Castle[428] has reviewed the development of knowledge concerning the gastric intrinsic factor and its relation to pernicious anemia. He concludes, after a scholarly exposition with extensive bibliography, that he is "sure that there is now general agreement at least on the present state of uncertainty about the nature and function of the intrinsic factor."* He presents several theories, favoring the "catalyzed absorption theory" which assumes that intrinsic factor directly and specifically facilitates the absorption of vitamin B_{12} by the intestinal wall. According to Castle, pernicious anemia "would not develop if the patient could effect daily the transfer of a millionth of a gram of vitamin B_{12} the distance of a small fraction of a millimeter across the intestinal mucosa and into the blood stream. This he cannot do, principally as a result of failure of his stomach to secrete into its lumen some essential but unknown substance."*

In man the intrinsic factor is excreted by the gastric fundal glands and is probably a mucoprotein which has antigenic properties. It is protected from digestion by vitamin B_{12} and by food and consists of two components, one binding vitamin B_{12} and the other attaching itself to the intestinal mucosa. The latter component requires calcium ion, and therefore versenate and phytate inhibit vitamin B_{12} absorption. In addition there is some evidence that the intestinal mucosa contains a vitamin B_{12} acceptor which may become saturated by large doses of vitamin B_{12} and prevent further absorption. Vitamin B_{12} is stoichiometrically bound to intrinsic factor, is removed from food, and is absorbed mainly in the ileum. The intrinsic factor is probably absorbed with it. Vitamin B_{12} absorption is increased by the administration of sorbitol, thyroid, cortisone, and intrinsic factor if it is lacking and during pregnancy. Vitamin B_{12} absorption is decreased if intrinsic factor is absent, if intestinal pH is low, or if the intrinsic factor-vitamin B_{12} complex is used up prior to absorption. The speed of absorption depends on the amount of vitamin B_{12}. A small amount may take up to 4 hr., whereas massive amounts are rapidly absorbed. Much of the vitamin is stored in the liver and is liberated when the liver parenchyma is damaged. Other storage organs include the pancreas, spleen, heart, and kidney. In the kidney some of the vitamin B_{12} is probably reabsorbed. For vitamin B_{12} uptake by bone marrow a special serum factor may be necessary in addition to the intrinsic factor. Orally administered vitamin B_{12} is excreted in the bile, feces, and urine.[429, 430]

One of the fundamental problems in pernicious anemia is the question of why the intrinsic factor is diminished or absent. Pathologists have long been aware of the gastric atrophy found in pernicious anemia. From many statistical data one can get the impression that pernicious anemia is a familial disease characterized by varying degrees of gastric atrophy, which in some members of the family produces pernicious anemia but in the majority leads to clinically undetectable diminished intrinsic factor production. The latter are the potential pernicious anemia patients should factors appear which by their summation lead to vitamin B_{12} deficiency or to further intrinsic factor diminution, such as senile atrophy of the gastric mucosa, gastritis, inadequate diet, or hypothyroidism.

In the serum most of the absorbed vitamin B_{12} is bound to α-globulin, a complex called erythroglobulin. Free vitamin B_{12} is probably loosely attached to β-globulin. Vitamin B_{12} clearance studies show an increased binding capacity in myelogenous leukemia, whereas in lymphatic leukemia and in liver disease the binding capacity is normal.

Symptoms and signs

The symptoms of the disease are as follows. For a long period patients show a gradually increasing fatigue, with loss of appetite, vague symptoms of gastric disturbance achylic in nature, with burning of the tongue or about the gums. These patients at this time display the so-called Hunter tongue or Moeller glossitis, with rhagades about the mouth, gingivitis, marked dental caries, and extreme pallor. In these cases there is noted the light yellowing

---

*From Castle, W. B.: New England J. Med. **249:** 603, 1953.

of the sclerae and other signs of possible hemolytic icterus. They show a golden yellow serum due to bilirubinemia as determined by the alcoholic (indirect) reaction of van den Bergh. Urobilinuria and urobilinogenuria are present.

There is usually complete achylia. The blood may or may not in the beginning show anemia, hyperchromia, and increase in size of red cells, whereas the hemoglobin and total red cell values persistently remain normal. One must emphasize at this point that the most significant indication of pernicious anemia is the **increase in the size of the red cells.**

Patients may develop nervous symptoms such as a numbness in the finger tips which is due to disturbances in the terminals of sensory nerves. They also have disturbances in taste and slight difficulty, too, with an otherwise good memory; they may show beginning impotency, perhaps slight unsteadiness in the gait, decreased or increased patellar reflexes, and Babinski, paralytic, or spastic ataxia.

There is another very remarkable phenomenon in pernicious anemia known as a remission—an unaccountable and sudden return to normal without any treatment.

The outcome of these cases is now favorable, but, as stated before, pernicious anemia was formerly considered a severe fatal anemia, preceded by a failing heart and edema of the lungs and subcutaneous tissues. Many of these patients developed the well-known funicular myelosis or subacute combined degeneration of the cord, a severe spastic or tabeslike status, complicated with decubitis and bladder and intestinal paralyses. Many patients showed preagonally hemorrhagic diatheses, at times definite retinal hemorrhages. Occasionally, a patient dies with symptoms that are highly suggestive of aplastic anemia.

Blood picture

The blood is watery, and consequently spreads are very thin. The total white cell count is low, usually around 4000/c.mm. The red cell count is low, 2,000,000-3,000,000/c.mm., sometimes as low as 320,000. The mean corpuscular hemoglobin (MCH) is high because of the disproportion between the count and the hemoglobin. The blood serum has the golden yellow appearance so well described by Naegeli, with the alcoholic (indirect), van den Bergh test **positive** and the (direct) test **negative.** There is in this disease a megalocytic blood picture with anisocytosis, poikilocytosis, and all degenerative forms of blood cells. The red cells, as just stated, are always definitely enlarged. One finds large hyperchromic cells, megalocytes. These cells have an increased cell volume and are completely filled with hemoglobin. The Price-Jones curve has a wide base, and the peak shows a displacement to the right. The red cells also show polychromasia, basophilic stippling, and Howell-Jolly bodies as well as nucleated forms. The reticulocyte count is low.

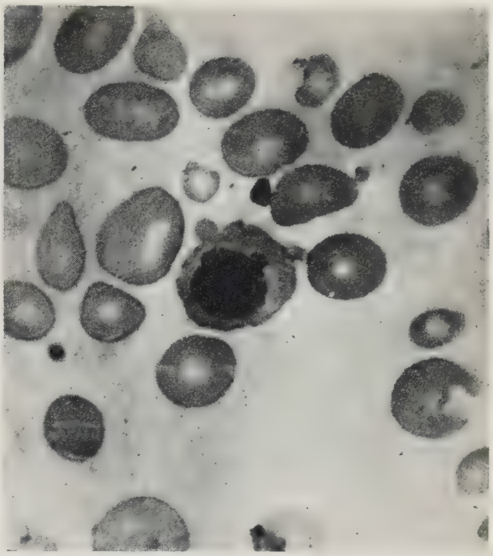

Fig. 421. Blood film of pernicious anemia showing hyperchromia, anisocytosis, poikilocytosis, macrocytosis, and a megaloblast. (×950.)

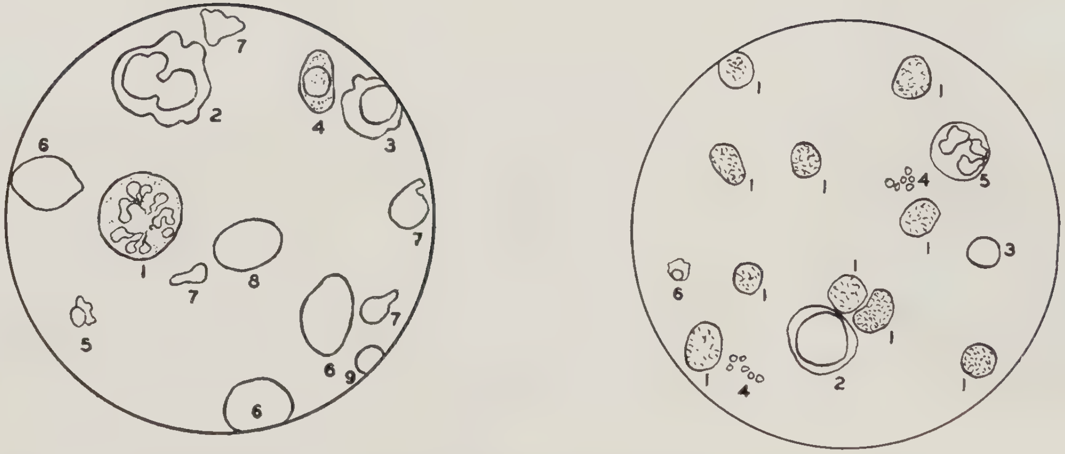
The white cells show neutropenia and lymphocytosis. **The nuclei of the neutrophils are highly segmented.** There are sometimes 6-8 segments to the cell, united to each other by fine stringlike connections. Arneth called this his characteristic right shift or **hypersegmentation.** These cells are also larger than normal and are called macropolycytes. The hypersegmentation is probably not a sign of old age but rather represents an abnormal configuration.

Blood platelets are absolutely decreased and are irregular in form and size. The entire blood picture has been called the **Naegeli syndrome.**

Blood crises are present in the beginning of the remissions of pernicious anemia or shortly before death. Here are seen many polychromatic and nucleated reds and also many regenerative leukocytes such as juvenile cells, myelocytes, promyelocytes, and even myeloblasts. The hemogram shown in Table 247 is from a blood crisis during pernicious anemia.



Advanced pernicious anemia

Before treatment

(Blood film; Giemsa stain; ×950)

1. Giant hypersegmented neutrophil
2. Monocyte
3. Lymphocyte
4. Cabot ring body and basophilic punctation in a macrocyte
5. Large blood platelet
6. Megalocyte
7. Poikilocyte
8. Polychromatic megalocyte
9. Polychromatic normocyte

Note anisocytosis, poikilocytosis, polychromasia, basophilic punctation. Erythrocytes are macrocytic hyperchromic.

After therapy

(Brilliant cresyl blue; Giemsa stain; ×950)

1. Reticulocytes
2. Plasma cell
3. Polychromatic erythrocyte showing no reticulum
4. Blood platelets
5. Segmented neutrophil
6. Polychromatic microblast

Advanced pernicious anemia

Before treatment

After therapy

Fig. 422

Table 247

Basophils	*Eosinophils*	*Myelocytes*	*Juvenile cells*	*Stab cells*	*Segmented cells*	*Lymphocytes*	*Monocytes*
–	–	–	2	15	68	7	8

For every 100 leukocytes there were 1385 polychromatic normoblasts, 25 polychromatic macroblasts, 3 polychromatic megaloblasts, and 2 cells in mitosis.

There were marked karyorrhexis, coarse basophilic punctation, Howell-Jolly bodies, marked polychromasia, marked anisocytosis, and occasional myelocytes.

It is the custom to call a blood picture, in the absence of clinical symptoms, a **pernicious anemic blood picture** in reference to the above findings but not necessarily a case of **pernicious anemia.** It is interesting to note that from 3 to 4 days (maturation time of red blood cells) after the institution of liver therapy, there are marked polychromasia and a marked increase in the reticulocytes. The red cells return slowly to their normal form and color. The existing hemolysis ceases. There is also a rise in the hemoglobin, together with a rise in the number of red cells, but the rise of the red cells is faster than the rise of the hemoglobin, thus making the MCH fall. Leukocytes take on the aspect of hyperleukocytosis, often accompanied by eosinophilia.

Hypersegmentation of neutrophils: It has been known for a long time that there is a greater segmentation of the neutrophilic nucleus in pernicious anemia than in any other type of anemia. This was seen in the Arneth count when the number of cells with nuclei containing 3, 4, 5, or more segments is much higher than in normal blood. The increase in the cells of groups 4 and 5 of the Arneth count has been described by him as a shift to the right and is characteristic of the megaloblastic anemias. Some writers definitely state that this phenomenon is absolutely diagnostic of pernicious anemia, but it is difficult to agree with this statement in the light of the authoritative literature on the subject. In a monograph by Sturgis and Isaacs,[431] the following statement covers this question exceedingly well: "The polymorphonuclear neutrophils in pernicious anemia may have a greater percentage of nuclei with more lobes than normal; that is, the percentage of cells containing nuclei with 3, 4, 5, or more lobes is much greater in the blood of patients with pernicious anemia than in normal blood. This corresponds to what is described as a shift to the right in the Arneth count, and it occurs frequently when the anemia is severe. While some regard this as diagnostic of pernicious anemia, it is not characteristic of this condition alone as the same finding may be observed in other types of anemia. A shift to the left takes place during the early stages of the remission."*

Fleming[432] pointed out that the conditions in which a shift to the right occurs are pernicious anemia, sprue, and lymphocytic leukemia. Piney states that it occurs in certain cases of Hodgkin's disease prior to x-ray therapy. Davidson and Gulland[433] state that the cell bodies of the polymorphonuclear leukocytes are oval and not round in this condition; that this applies to both the large forms and those of ordinary size; further, that this change is most commonly found in severe cases and may affect all or nearly all the cells of that type to be seen in the blood film.

There are certain highlights in the diagnosis of this disease which must be emphasized.

1. Anemia often severe.
2. Diminution of blood platelets.
3. Erythrocytic changes, particularly increase in size.
4. Variations in size of the red cells.
5. Basophilic punctation, Cabot ring bodies, and polychromasia.
6. Occasional finding of megaloblasts.
7. Finding of normoblasts or nucleated red cells.
8. Neutropenia with high segmentation of the neutrophils, or Arneth's shift to the right.
9. Response of such cases to specific treatment.
10. Marked increase of reticulocytes first, after liver therapy, followed by a rise in the number of red cells before the hemoglobin begins to rise and consequent lowering of the MCH is highly suggestive of the accuracy of the diagnosis of morbus addisonii.
11. Macrocytosis should attract one's attention to this disease even before an anemia is noted.
12. A high or even a normal white count almost rules out this disease in cases of suspected anemia. In all cases one finds a lowered white blood count, sometimes down to 4000/c.mm.
13. It is claimed by Rous and Robertson[434] that the small red cells or microcytes with pointed tails, which may be called poikilocytes, are indicative of increased blood destruction.
14. Many basophilic punctated red cells are seen in this disease just as they are found in lead

---

poisoning, but, as a rule, **polychromatic young red cells** are not found in Addison's anemia except at the onset of improvement of a treated case. It is for this reason that the count of the reticulocytes is very important.

15. There are very low red blood counts in this disease, sometimes as low as 500,000.
16. The white count is very low due to the failure of the bone marrow to produce neutrophils. In other words, the lymphocytes are not interfered with, whereas the neutrophils are lowered. Consequently, there is a picture of relative lymphocytosis. The higher the lymphocytosis, the severer is the prognosis, for the reason that the higher the lymphocytes, the more obvious it is that the bone marrow function for the manufacture of the neutrophils is partially destroyed.
17. As to the size of the red cells, the majority exceed 8.5μ in diameter.

The red cell survival time is shortened to ½ to ⅓ of the normal time. Pernicious anemia has a hemolytic component, and the red blood cells show increased hemolysis in hypotonic saline (incubated or using saponin). The plasma of patients with pernicious anemia also contains a hemolysin which acts on normal red blood cells transfused into untreated pernicious anemia patients. Because of the hemolytic component there is an increase in urobilinogen excretion and lowering of serum haptoglobin.

Reticulocyte response after erythrocyte maturation factor therapy: One of the most important phenomena in connection with the prognosis of this disease is the reticulocyte response after liver or other erythrocyte maturation factor therapy. In other words, after the use of these standard remedies, reticulocytes increase markedly in the peripheral blood. This is due to the normal maturation of the nucleated red blood cells in the bone marrow. This reticulocyte response does not show in the first 5 days of treatment for the reason that in this period the megaloblasts are developing into normal erythroblasts in the bone marrow. After the fifth day, there is a rapid increase in the number and percentage of reticulocytes. After the ninth to tenth day, there is a decrease in the percentage of reticulocytes, accompanied by an increase in the total number of red blood cells. From time to time thereafter there are increases in the percentage of reticulocytes due to the stimulation of blood formation. The greater the dose of the remedial agent used, the more rapid will be the reticulocyte response. This is dependent, too, upon the route of administration whether by mouth or by injection. The depth of the anemia in part determines the height of reticulocytosis; the more anemic the patient, the higher the reticulocyte response will be.

Bone marrow findings

There is marked (up to 10-30 times normal) erythroid hyperplasia, most of the cells belonging to a pathologic series, the megaloblastic series, which can be followed from the youngest promegaloblast to the more mature macronormoblast. These cells show nuclear-cytoplasmic asynchronism as well as a disturbance of the normal nuclear-cytoplasmic ratio. They crowd out most of the normal erythropoietic elements. The biochemical lesion responsible for the megaloblastic series is not known. Despite the fact that both folic acid and vitamin B_{12} are required for nucleoside synthesis, megaloblasts do not show a deficiency in desoxyribonucleic acid nor in ribonucleic acid. The marrow shows a high percentage of ineffective erythropoiesis. There appears to be an abnormal block or delay in the division of the erythroblasts while the division of proerythroblasts continues. Proerythroblastic cells acquire hemoglobin and retain their nuclei which fail to undergo pyknosis. The prime defect may be one of division rather than one of maturation. The delay in mitosis, the abnormality of cells, and the large number of ineffective cells lead to a marked erythroid hyperplasia which, despite its magnitude, is inadequate. Under the influence of antianemic therapy the megaloblasts begin normal division so that for a limited period (3 days) intermediate forms appear, and then finally normal erythropoietic elements can be found. The myelocytic elements are also involved in this process, and large myelocytes and giant metamyelocytes appear which are the result of abnormal division at the myelocytic level. These cells are apparently able to mature but are not able to divide. The abnormal leukocytic forms persist even after the erythroid series has returned to normal following therapy. Abnormal megakaryocytes as well as abnormal reticulum cells are noted.

Anatomically the principal change in the bone marrow in pernicious anemia is the replacement of the fatty marrow of the long bones with a soft red marrow which in the normal adult is restricted to the flat bones. Davidson and Gulland[435] found that the number of white cells in the bone marrow is greater than might be expected from the constant leukopenia present in the peripheral blood in these cases. Davidson and Gulland found also that the segmented neutrophils were reduced in number in the bone marrow and that the predominant type of leukocyte present was the myelocyte.

Nonhematologic findings

Examination of gastric juice: Examination of the gastric juice shows histamine-fast achylia. Stomach biopsy reveals atrophy of the mucosa. A very occasional case of true pernicious anemia may have free acid but will still lack intrinsic factor. This is usually seen in the rare pernicious anemia in childhood.[438] The occasional presence of hydrochloric acid and absence of gastric atrophy has led to a reappraisal of the gastric lesion in pernicious anemia with the result that Magnus[436] points out that the basic defect must be an inherited enzymatic defect of certain cells which prevents utilization of the intrinsic factor or absorption of vitamin B_{12}. It is this defect then which leads to atrophy of the gastric mucosa. According to Magnus[436] and Dameshek[437] this metabolic intrinsic cellular abnormality may at one stage be reversible or may go on to irreversible neoplasia. This process is seen in the cases of pernicious anemia which go on to polycythemia, leukemia, or cancer of the stomach.[439]

Another approach to diagnosis in the treated patient with pernicious anemia is the study of exfoliated material obtained by gastric lavage.[440] Rubin and Massey[441] have demonstrated a cell type in such washings which appears specific for pernicious anemia and which was found in 20 of 21 patients who had been under therapy for years. These cells are markedly enlarged atypical columnar epithelial cells with nuclei approaching twice normal size.

Examination of urine[450]**:** Olmstead and Hirschboeck[442] studied the fasting urorennin excretion in 50 patients with pernicious anemia and found that none of these patients excreted more than 0.5 rennin unit/10 ml. urine. In a control group aged 40-90 yr., 13 excreted less than 0.5 rennin unit, but the others excreted more than this. Their conclusions are that, if the morning urorennin excretion exceeds 0.5 rennin unit, it is likely that pernicious anemia is quite remote. On the other hand, excretions below 0.5 unit only imply the possibility of pernicious anemia but do not make a diagnosis.

Uropepsin determinations in urine show a similar fall. Urine amino acid assays reveal an increase in taurine. There is evidence that formiminoglutamic acid increases markedly in the urine of folic acid-deficient patients (from the normal of about 30 μg/ml. urine to as much as 275 μg/ml. urine). For assay methods of folic acid and formiminoglutamic acid see references.[442a, 442b, 451]

Examination of serum[449]**:** The serum findings include a low vitamin B_{12} content associated with an increased serum iron level and normal serum proteins. As in all hemolytic anemias, the haptoglobulin level is diminished. The prothrombin level may be low. Characteristically, the lactic dehydrogenase activity is about 10 times normal and may be related to the aforementioned extensive ineffective erythropoiesis in the bone marrow since megaloblasts are rich in this enzyme and probably release it when disintegrating.

Treatment

Folic acid therapy: Some patients show a sensitivity to liver—inflammation around the needle point after injection, together with a generalized itching sensitization of the skin. In some such cases, folic acid has been used. This is a vitamin which is known at this time to be very useful in the treatment of general macrocytic anemias, particularly nutritional anemia in the southern part of the United States and the tropics. It is highly useful in sprue, in pernicious anemia of pregnancy, in anemias associated with chronic alcoholism, and in carcinoma of the stomach.

It has been well established that folic acid will cause a complete hematologic response and will maintain blood levels in patients with pernicious anemia. However, the neurologic manifestations of this disease may continue to progress with folic acid therapy even though the hematologic response is satisfactory. For this reason, the use of folic acid **alone** is not recommended for the treatment of pernicious anemia.

Vitamin B_{12} therapy: In 1948 Smith[443] and Rickes and co-workers[444] isolated crystalline vitamin B_{12} from liver. It was found that infinitesimally small amounts of this substance were effective in restoring normal hematologic values in pernicious anemia patients in relapse. The dosage schedule is a minimum of 1 μg/day, but larger dosages are generally used. Blackburn[445] and Piney[446] have reviewed the modern treatment of pernicious anemia in excellent fashion.

A great deal of attention has been centered on the use of vitamin B_{12} orally, especially when combined with mucosal extracts of hog stomachs.[447] Small doses of vitamin B_{12} below 20 μg are ineffectual when given alone, but when vitamin B_{12} is combined with intrinsic factor containing mucinous materials from hog stomach, responses are optimal or suboptimal. Suboptimal dosages may mask symptoms until irreversible neurologic changes have taken place. The use of minimal dosages is decried because this alters the bone marrow picture sufficiently to make diagnosis impossible.

If there is no response to the administration of hog stomach and vitamin B_{12}, human gastric juice should be substituted. It is interesting that antibodies to human intrinsic factor have been shown to exist so that the possibility of an autoimmune type of pernicious anemia has to be considered.

Schilling[448] described a test for intrinsic factor in which he attempted to solve the dilemma of diagnosis in treated patients with pernicious anemia. The test consists of the administration of 0.5μc radioactive vitamin B_{12} (B_{12} Co^{60}) orally, followed in 2 hr. by 1000 μg of nonradioactive vitamin B_{12} parenterally. In normal subjects radioactive vitamin B_{12} appears in the urine within 4-6 hr. after the oral dose, and this excretion continues for 24 hr. In pernicious anemia, no radioactive substance appears in the urine.

SYMPTOMATIC MEGALOBLASTIC ANEMIAS

Malabsorption syndromes

Sprue*

Sprue has been described as an insidious chronic, remittent catarrhal inflammation of the alimentary canal occurring particularly in Europeans who are residing or have resided in tropical or subtropical climates. Undoubted cases of sprue have been reported in persons living in temperate climates who had not visited the tropics. These cases appear in the literature as nontropical sprue.

The disease is characterized by stomatitis and a bare, raw, painful tongue, recurrent attacks of cramps and diarrhea, voluminous, frothy, acid stools, loss of weight, and a severe anemia of the pernicious type.

The onset is usually insidious and manifests itself first by soreness of the buccal mucosa and vague digestive disturbances. The course is afebrile. The untreated patient gradually becomes weak, emaciated, irritable, and deadly pale.

The etiology is unknown. Only the concept of a deficiency disease has been able to withstand prolonged investigation. Castle, Rhoads, and collaborators, while working in Puerto Rico, confirmed the belief that deficient diets frequently antedate the onset of clinical sprue. Surely the disease is not contagious. The theory of the "monilia psilosis" as a causative agent has been discarded.

The disease is endemic in the East Indies, in South China, in India and Ceylon, in the West Indies, in Australia, in Japan, Korea, and the Philippine Islands. Its occasional occurrence in the United States is an accepted fact.

In a series of 150 cases studied in Puerto Rico, there were 121 caucasoids, 26 mulattoes, and only 3 Negroes. The disease appears to be, therefore, extremely rare in the Negro race. One third of the patients were less than 40 years of age, a point of difference from true addisonian anemia.

In general appearance some of the older patients presented strong resemblance to persons with pernicious anemia. Loss of subcutaneous fat and wrinkling and pigmentation of the skin, especially of the arms and legs, favor the diagnosis of sprue. In contrast to pernicious anemia the spleen was always normal or small. Although purpuric or scorbutic spots were occasionally found, retinal hemorrhages were uniformly absent.

The occurrence of osteoporosis and osteomalasia, reported as a common finding in nontropical sprue, was not found in the series of 150 cases already mentioned.

Investigations of the glucose tolerance showed uniformly a flat curve, favoring the theory of deficient intestinal absorption and making the hypothesis of a possible pancreatic disease less important in the understanding of sprue. Moreover the pancreas has been found normal in a high percentage of cases studied at autopsy.

The anemia in sprue is macrocytic, usually hyperchromic, and rarely hypochromic. The mean cell volume averages 123.6 c.μ. Nucleated red cells are very rarely found. Eosinophils are reduced. The white cell count is below normal, averaging 5280. See Table 248.

Studies of the aspirated sternal marrow yield interesting data. Megaloblasts are frequently seen. Usually there are more erythroblasts than normoblasts. Megakaryocytes, plasma cells, and monocytes are very rarely seen.

---

*This discussion was contributed through the courtesy of Dr. Ramón M. Suárez, of the Hospital Mimiya, Santurce, Puerto Rico. The tables and the photomicrograph of the bone marrow were also furnished by Dr. Suárez. Dr. Suárez has had an unusual opportunity to study this disease in Puerto Rico.

Many of the erythroblasts are of the intermediate type. There is also a diminution in the amount of fat and in the myelogenous elements. Numerous Howell-Jolly bodies are seen in the bone marrow and peripheral blood supposedly due to the associated splenic atrophy.

Serum vitamin B_{12} levels are usually normal, whereas folic acid absorption is abnormal.

In Table 249 are shown the differential counts of the nucleated elements in the aspirated sternal marrow of sprue cases before treatment and again 10 days and 2 mo. following the institution of parenteral liver therapy. The erythroblastic elements, originally 41.73%, gradually diminished to 15.83%; the myeloblastic cells increased from 53.5% to 78.79%; the lymphoblastic elements in the

marrow remained stationary during the observation period of 2 mo.

The van den Bergh test is the same in sprue as it is in pernicious anemia; i.e., the test points to an increased degree of blood destruction. There is approximately normal or slightly increased resistance of red cells to hemolysis by hypotonic sodium chloride solution, which is just about what is found in pernicious anemia. A reduction in blood platelets may occur, but it is variable and not to be depended upon as a diagnostic measure.

The most striking pathologic finding at autopsy is the almost total disappearance of the subcutaneous fat. The intestines are markedly thinned out, this atrophy especially affecting the mucosa. All internal organs are smaller, especially the liver and heart. Histopathologic changes of a chronic or ulcerative colitis were found in 30% of the patients.

Clinically, hematologically, and pathologically many of the cases of sprue are indistinguishable from pernicious anemia. Low blood calcium figures have been reported in sprue, which is not the case in pernicious anemia. Achlorhydria, an almost constant finding in pernicious anemia, is found in only 30% of sprue cases. Young children and adolescents are frequently affected with tropical sprue and very rarely if ever with pernicious anemia. Cord changes or neurologic manifestations, on the other hand, are extremely rare (about 2%) in sprue.

The 2 most important factors in the treatment of sprue are an appropriate diet and adequate liver or folic acid therapy. Ashford[452] insisted on the necessity of a high protein, low fat, and low carbohydrate diet. Liver extract should be administered parenterally. Both the diluted and the concentrated liver extracts have been found highly effective in all cases of sprue characterized by a macrocytic anemia, whether hyperchromic or hypochromic. Sprue is more resistant to treatment than is pernicious anemia and requires larger doses of liver, vitamin B_{12}, folic acid, and cortisone.

Megaloblastic anemia of Diphyllobothrium latum infestation

Discussion of anemia due to the *Diphyllobothrium latum* has been carried on in medical literature for some time. The question that has agitated the writers on this subject is whether this fish tapeworm causes the anemia which is so like a case of pernicious anemia or whether, as Magath[453] has stated, the presence of *Diphyllobothrium* is considered only as a trigger that sets off the illness. Schauman,[454, 455] the leading European investigator of this problem, maintains that *Diphyllobothrium* is capable of causing an anemia which is not distinguishable from true primary pernicious anemia, and that the reason the incidence of the disease is so small is that the "ordinary host is refractory toward the anemia-causing agent of the tapeworm." Piney[456] has called attention to the close resemblance between this anemia and true primary pernicious anemia. He believes that this condition may be elicited in some by the toxins of the fish tapeworm but thinks a constitutional predisposition probably exists in these patients. Birkeland[457] reviewed all the foreign as well as the American literature on *Diphyllobothrium* anemia, and after presenting the observations and opinions of apparently all who have written on this subject, in an unbiased but critical manner, concluded that the anemia occurring in symbiosis with an infestation by *Diphyllobothrium* is probably not due to any specific substance elaborated by this parasite but to a constitutional factor which would probably cause this type of patient to have a pernicious anemia without the presence of a parasite, granting that there occurs some unknown precipitating factor in this disease. In other words, he considers patients who suffer and survive *Diphyllobothrium* anemia as having had an abortive form of true primary pernicious anemia. Von Bonsdorff[458] suggests that the pernicious anemia picture of *Diphyllobothrium* infestation is due to two possible mechanisms. One involves the competition of parasite and host for vitamin B_{12}; in the event that the worm wins in this race, a deficiency develops in the host. An alternative or contributory mechanism is that intrinsic factor production may be diminished if the parasite is located high up in the small intestine. If the parasite moves lower down in the gastrointestinal tract, the pernicious anemia picture disappears.

Isaacs, Sturgis, and Smith studied a patient with a fish tapeworm infestation who had a typical blood and clinical picture of primary pernicious anemia which was amenable to liver therapy before removal of the tapeworm and who had no relapse of the anemia following the eradication of the parasite, even when liver therapy was stopped. Seyderhelm has demonstrated that the ground-up body of the fish tapeworm has a hemolytic action both in vitro and in vivo. Hunnicutt[459] has given a report on a very interesting case of a native of Finland who had a disease which was singularly like true pernicious anemia and cleared up under liver therapy and who later showed eggs and segments of worms. The diagnosis can be suspected when the characteristic anemia occurs in young persons in the presence of free hydrochloric acid, but it must be confirmed by examination of the stool.

In the megaloblastic anemias due to malabsorption are included the anemias that ensue from gastrectomy,[461, 462] blind loop operation,[460] regional ileitis,[460] etc. All these are believed to be due to altered bacterial flora (the achlorhydric stomach or gastric stump contains bacteria) which interferes with vitamin B_{12} absorption or utilizes vitamin B_{12} prior to absorption.

The diagnosis can be made in the presence of a suitable history and clinical findings and by a modification of the Schilling test. Addition of intrinsic factor does not improve absorption of radioactive vitamin B_{12}, but a course of tetracycline is followed by adequate absorption.

Megaloblastic anemia of pregnancy

The most common anemia in pregnancy is hypochromic in type, but in a large series reported, hyperchromic anemia occurred in 1 per 240 pregnant patients. Much higher incidence figures can be found in the recent literature, such as 1 in 67 or even higher. As a group, these patients are usually multiparous women who not only have a severe anemia but also a high incidence of premature births, hydramnios, and toxemia, conditions which lead to a high incidence of neonatal death (6%).

The anemia is frequently mixed (dimorphous). The megaloblasts are of the intermediate type, and there is evidence of iron deficiency. Serum vitamin B_{12} levels are normal. Intrinsic factor deficiency is not present, and folic acid absorption is normal. The cause of this type of anemia is not known. There is usually no evidence of malnutrition or of borderline nutrition which could be aggravated by pregnancy. The lowering of the serum vitamin B_{12} level in pregnancy is not related to the pathogenesis of this anemia. Folic acid treatment is curative.

Hormonal or metabolic disturbances have been suggested as being responsible for the anemia. Many years ago Vollmer and Gordan[463] showed a slight reduction of the red blood cell count of the female rat receiving pregnant mare's serum.

Megaloblastic anemia following medication (Dilantin)

According to Listberg and others,[464] most of the reports of megaloblastic anemia following anticonvulsant therapy appear in the British and Scandinavian literature. He reports one of the first cases in the American literature. The cause of the anemia appears to lie in an interference with the metabolism of folic acid and vitamin B_{12} similar to the one produced by folic acid antagonists. Antimalarial drugs such as pyrimethamine have also produced megaloblastic anemia after prolonged administration.

Other macrocytic and megaloblastic anemias

Megaloblastic or macrocytic anemias have been described in many conditions such as diseases of the liver, pancreas, and kidney, as well as in multiple myeloma, leukemia, polycythemia, and hemolytic anemias. The hyperchromic anemia accompanying hypothyroidism has long been recognized.

Folic acid acts as a coenzyme for a great number of intracellular metabolic reactions and is involved in the metabolism of thymine, purines, and pyrimidines, as well as uridylic acid (orotidylic acid) and folinic acid, all taking part in the formation of ribonucleic acid and desoxyribonucleic acid. There have been reports of megaloblastic anemias resulting apparently from metabolic defects involving such substances as folinic acid, ascorbic acid, uridylic acid, and thymine. The achrestic anemia described by Israels and Wilkinson may well fall into this group.

Macrocytic or megaloblastic anemia of hepatic cirrhosis

Severe liver disease may be accompanied by microcytic anemia, by simple macrocytosis without anemia, or by megaloblastic anemia.[466-468] Hypochromic anemia occurs only secondary to bleeding, whereas hemolytic anemia may be related to secondary hypersplenism. Various authors report the frequency of macrocytic and megaloblastic anemias as varying from 32-80%. The assumption that the degree of anemia is related to the degree of liver damage is not accepted by all authors. The bone marrow in cirrhosis is hyperplastic and shows erythroid hyperplasia, due mainly to an increase in normoblasts and macronormoblasts. Megaloblasts are rare, and the occurrence of true pernicious anemia in hepatic cirrhosis is doubtful, though reported by Rohr and others. Several etiologic factors can be mentioned for the occurrence of this anemia. The stomach may show alcoholic gastritis associated with depressed intrinsic factor content. The portal hypertension may lead to difficulty in absorption. The hypothesis that the liver parenchyma cannot fully accept, store, or release the antianemic factor cannot be supported, as liver extract obtained from cirrhotic livers converts the megaloblastic marrow of pernicious anemia to normal. On the other hand hepatic dysfunction leads to dysproteinemia, which in conjunction with hypovitaminosis may produce an alimentary type of macrocytic anemia. Bingham[467] divided the macrocytes into 3 types—thin, thick, and target. He felt that the thin macrocyte was specific for liver disease.

Endocrine macrocytic anemia

The anemia of hypothyroidism may be related to the frequent finding of gastric achylia in hypothyroidism, which also leads to some difficulties in vitamin B_{12} absorption.

NORMOCYTIC NORMOCHROMIC ANEMIAS

CLASSIFICATION

Hemolytic anemias
Aplastic or hypoplastic anemias
Myelophthisic anemia (myeloproliferative syndrome)
Anemia of pregnancy
Anemia of infection
Anemia of uremia
Anemia of endocrine disturbances
Anemia of avitaminosis

HEMOLYTIC ANEMIA

There are a number of blood dyscrasias which are grouped together as due to increased blood destruction. Paroxysmal hemoglobinuria, familial and acquired hemolytic jaundice, and sickle cell anemia are due to increased susceptibility of the red blood cells to destruction. There is a hemolysin present in the plasma in paroxysmal hemoglobinuria. In sickle cell anemia and hemolytic jaundice, in which there is a physical peculiarity of the erythrocytes, precise knowledge of its relation to increased blood destruction is lacking, although advances in the knowledge of "molecular disease of hemoglobin" has given us a new lead as to the basic disturbances.

All cases of hemolytic anemia have in common increased blood destruction and anemia. Hemolytic anemias may be divided into acute, subacute, and chronic types. The acute cases are due to malaria and other protozoa, bartonellae, bacterial toxins, chemical agents such as phenylhydrazine, saponin, trinitrotoluene, dinitrobenzol, aniline, amido and nitro compounds of phenol, benzol, toluol, lead, etc., snake venoms, extensive burns, and mismatched transfusions of isoagglutinogens A and B. All other types are those due to intragroup hemolytic transfusion reactions and hemolytic disease of the newborn. The chronic hemolytic anemias are classified as sickle cell anemia, chronic or acquired hemolytic jaundice, Cooley's anemia, and cases found with other chronic diseases such as pernicious anemia, Hodgkin's disease, and carcinomatosis.

Classification

Based on the foregoing, hemolytic anemias may be classified according to their clinical course into (1) acute, (2) subacute, and (3) chronic.

On the basis of etiology they may be classified into anemias due to intracorpuscular defects and those due to extracorpuscular defects.

- Intracorpuscular defects
  - Hereditary spherocytosis
  - Enzyme-deficiency hemolytic anemias
  - Hereditary (congenital) nonspherocytic hemolytic anemia
  - Other congenital hemolytic anemias (Heinz body)
  - Thalassemia
  - Paroxysmal nocturnal hemoglobinuria and paroxysmal cold hemoglobinuria
  - Hemoglobinopathies
  - Hereditary elliptocytosis (ovalocytosis)
  - Pernicious anemia
- Extracorpuscular defects
  - Antibodies: isoimmune and autoimmune
  - Infections: bacterial, viral, and parasitic
  - Toxins: snake venom
  - Physical agents: burns
  - Hypersplenism

Features of all hemolytic anemias and methods of investigation

Red cell survival time

The common denominator of all hemolytic anemias is the increased rate of blood destruction and the shortened life span of red blood cells. The normal life span of the red blood cell is 120 days plus or minus 20 days.

Ashby survival technic: The Ashby technic of differential agglutination requires the administration of compatible donor cells which nevertheless differ in type from those of the recipient. O cells for instance can be given

Fig. 424. Hemolytic syndromes—laboratory differentiation. Peripheral blood (I) and the marrow (II) indicate a hemolytic process. Osmotic fragilities (III) differentiate hereditary spherocytosis and acquired hemolytic anemia, on the one hand, from thalassemia, sicklemia, and iron-deficiency anemias on the other. Hereditary spherocytosis (H.S.) and acquired hemolytic anemia (A.H.A.) are differentiated from each other by incubated osmotic and mechanical fragility tests. Cells from hereditary spherocytosis show a pronounced increase in fragility (broken line). Cells from acquired hemolytic anemia show less change and usually assume an asymmetric curve (dotted line) which may cross over the normal incubated control. If the diagnosis is still not evident, immunologic tests (IV) are done. (From Wright, Claude-Starr: Mod. Med. 22:78, 1954.)

to A, B, and AB recipients or M and N cells to N and M recipients. Despite the obvious serologic difficulties reliable results can be obtained if blood samples of the recipient are tested for survival of transfused cells by differential agglutination at regular intervals (daily to every third or fifth day).

Red cell survival time measured by isotopes: Glycine labeled with N^{15} can be used to measure survival time in vivo as it is incorporated into the heme of newly formed red blood cells. By this method it has been shown that the destruction of normal red blood cells is a function of their age. C^{14} can also be used to tag glycine. Another in vivo method of tagging utilizes Fe^{59}. $Na_2Cr^{51}O_4$ and Fe^{59} are employed to label a patient's own cells in vitro after incubation and these are then reinjected into the patient. Since Fe^{59} is reutilized after the destruction of red blood cells, the use of Cr^{51} is the preferable method. The isotope methods allow the measurement of the survival time of the patient's own cells in his own circulation as well as the localization of the site or sites of their destruction.

The tagged cells allow 3 methods of investigation: (1) injection of the patient's own tagged cells into himself, (2) injection of the patient's tagged cells into a normal compatible recipient, and (3) injection of compatible normal donor tagged cells into the patient.

In hemolytic anemias characterized by an intrinsic defect, methods 1 and 2 will show a shortened survival time, whereas method 3 will result in a normal survival time. The defect can thus be localized in the patient's own red blood cells, which are rapidly destroyed in a normal recipient.

In hemolytic anemias due to an extrinsic defect, methods 1 and 3 will result in a shortened survival time, whereas method 2 will give a normal survival curve. The defect thus lies in the patient's circulation which rapidly destroys normal donor cells.

In a combined defect, that is extrinsic and intrinsic, both methods 2 and 3 will exhibit shortened steep curves as does, of course, method 1.

Hemolysis

There are 2 major methods of red cell destruction: (1) extravascular hemolysis and (2) intravascular hemolysis.

Extravascular hemolysis

In the aged cell, certain enzymatic changes[470] take place which lead to a decrease in adenosine triphosphate and coenzyme I, a process which ushers in the death of the cell. These cells are then engulfed by the macrophages of the reticuloendothelial system of the bone marrow, spleen, liver, lung, etc. and are destroyed so that their hemoglobin is freed. The iron is rapidly reutilized and is carried to depot organs by transferrin, whereas the porphyrin moiety is converted into free nonconjugated bilirubin. In the liver the latter is conjugated to glucuronic acid and is then excreted as conjugated bilirubin, which in the bowel is converted by the action of bacteria into urobilinogen and is excreted in the feces and urine.

Laboratory investigation of extravascular hemolysis

Schematic pathway of pigment

Extravascular breakdown → increased serum bilirubin → icterus → increased urine and fecal urobilinogen

Serum bilirubin

The indirect van den Bergh value is increased due to the presence of free (nonconjugated) bilirubin. The serum bilirubin depends on 3 factors: (1) rate of production, (2) liver function, i.e., its ability to conjugate, and (3) number of circulating red blood cells. An increase in the bilirubin level of more than 3 mg./day is evidence of increased blood destruction.

In newborn infants the liver is unable to conjugate bilirubin for several days, and therefore all bilirubin is indirect reacting.

Urobilinogen

Fecal urobilinogen: This is a colored pigment resulting from reduction of bilirubin. It depends not only on the rate of hemoglobin breakdown but also on the total red blood cell count and the total circulating hemoglobin. The hemolytic index represents the correlation of fecal urobilinogen to the total circulating hemoglobin.

$$\text{The hemolytic index} = \frac{\text{Fecal urobilinogen (mg./day)} \times 100}{\text{Total circulating Hb (gm.)}}$$

Normal: 100-200 mg./day.

Urinary urobilinogen: Urobilinogen is absorbed from the bowel into the blood stream but is excreted by the kidneys into the urine only if the plasma level exceeds the amount the liver is able to reconvert into bilirubin. The level of the urinary urobilinogen is, therefore, more a test of liver function than an indicator of increased hemolysis. Urinary urobilinogen on standing is converted into a dark pigment, urobilin.

Normal: 0-4 mg./day or production of a red color with Ehrlich aldehyde reagent in a 1:20 dilution.

Daily hemoglobin breakdown: 6 μg/day.

Intravascular hemolysis

Normally a small amount of blood is destroyed within the blood stream. The liberated hemoglobin is bound to plasma proteins called haptoglobins, which have a special affinity for hemoglobin. The haptoglobin-hemoglobin molecule is taken up by the reticuloendothelial system which splits the iron off the hemoglobin molecule and degrades the protein. The haptoglobin removed from the circulation is only slowly replaced (10 days) so that future waves of hemoglobin may find only a small amount of haptoglobin to bind and will thus be excreted by the kidney at a much lower serum hemoglobin level than is normally the case. If the free hemoglobin exceeds 140 mg./100 ml., the haptoglobin binding capacity is saturated so that free hemoglobin appears in the serum (**hemoglobinemia**) and in the urine (**hemoglobinuria**). The renal threshold for hemoglobin depends on the level of plasma haptoglobin[472-474] and on the tubular reabsorption which removes hemoglobin from the glomerular filtrate, creating a certain threshold level. If the haptoglobin level is low, as it is in newborn babies and some adults (Negroes) and in chronic hemolytic states, the renal threshold appears to be lowered, as free hemoglobin is excreted at relatively low plasma levels. In contrast with free hemoglobin, the hemoglobin-haptoglobin complex is not excreted by the kidneys. Some of the free hemoglobin is also taken up by the reticuloendothelial system and is converted to hemosiderin. Bruce and Lewis[471] have shown that disappearance of haptoglobin follows hemoglobin turnover of twice the normal rate.

Haptoglobin levels are raised in certain neoplasms with metastases, in infections, in Hodgkin's disease, in obstructive jaundice, and after steroid therapy so that the effect of hemolysis may be masked. A decrease in haptoglobin occurs in hemolysis whether extravascular or intravascular in nature, in liver disease, in infectious mononucleosis, and in congenital absence of haptoglobins.

Genetic studies have shown that 4 phenotypes of haptoglobin occur which are controlled by a pair of allelomorphic genes. The occurrence of ahaptoglobinemia may be due to this suppression effect.

Methods for determination of serum haptoglobin[475]

The following methods for the determination of serum haptoglobin are available: paper electrophoresis, titrimetric analysis, starch gel electrophoresis, immunoelectrophoresis, and spectrophotometry.

Paper electrophoresis[476]*—Nyman*

This method is based on the fact that when serum containing free hemoglobin and haptohemoglobin molecules is subjected to electrophoresis and then stained for peroxidase activity, 2 bands are seen. The band further away from the application point represents the hemoglobin-haptoglobin molecules, whereas the band closest to the application point represents free hemoglobin. A series of test tubes is prepared, each containing 0.1 ml. serum. To these test tubes hemoglobin solutions increasing in concentration by increments of 10 mg.% are added. These mixtures are then electrophorized and stained for peroxidase activity. The last strip which shows only one band of the hemoglobin-haptoglobin complex represents the highest hemoglobin concentration in which the entire hemoglobin is taken up by haptoglobin. The concentration of haptoglobin in the serum is expressed as the mg.% hemoglobin the serum is capable of binding.

Titrimetric analysis

Two methods are available, one in which an excess of hemoglobin is added to the constant amount of unknown serum and the other in which increasing amounts of the unknown serum are added to a constant amount of hemoglobin. In each case the hemoglobin binding capacity of the serum is measured and expressed in mg.

Starch gel electrophoresis and immunoelectrophoresis

These methods are useful in developing the genetic types of haptoglobin.

Spectrophotometric method for determination of serum haptoglobin—Owen, Better, and Hoban

The method presented here is based on the peroxidase activity of haptoglobin-methemoglobin complexes. Diluted serum is incubated with a standard methemoglobin solution to permit formation of a methemoglobin-haptoglobin complex. A buffered guaiacol solution and peroxide are then added, and this mixture is incubated in the dark. During this incubation, in the presence of peroxidase activity, the guaiacol is oxidized to a colored compound. The amount of this colored compound is determined spectrophotometrically. The amount of guaiacol oxidized, corrected for its nonenzymatic oxidation, is a measure of the peroxidase activity of the haptoglobin-hemoglobin complex and in turn of the haptoglobin content of the serum.

Reagents:

1. Guaiacol reagent.
   - (a) Dissolve 3.72 gm. guaiacol in about 700 ml. distilled water.
   - (b) Add 100 ml. 1M acetic acid.
   - (c) Adjust the pH of this solution to 4.0 by the addition of 1M sodium hydroxide and dilute to final vol. 1 L.

Alternately, the guaiacol may be dissolved in 0.1M sodium acetate buffer, pH 4.0, to a final volume of 1 L.

2. 0.05M Hydrogen peroxide.
   - (a) Prepare immediately before use by diluting a stock solution which has been previously standardized by titration against standard potassium permanganate. Commercial hydrogen peroxide is usually supplied as 30% solutions that are approximately 10M.
3. 0.15M Sodium chloride.
4. Methemoglobin solution, 50 mg./100 ml.
   - (a) Collect the erythrocytes from 30 ml. human blood by centrifugation and wash 3 times with 0.15M saline and measure the final packed volume.
   - (b) To 8 vol. these packed cells, add 3 vol. water and 1 vol. ether.
   - (c) Shake this mixture to effect hemolysis of the cells, centrifuge, and pipet off the hemolysate.
   - (d) Determine the concentration of hemoglobin in the hemolysate and dilute the hemolysate until the hemoglobin concentration is exactly 1 gm./100 ml.
   - (e) To 25 ml. of this solution add 10 ml. potassium ferricyanide (100 mg./ml.) to convert hemoglobin to methemoglobin.
   - (f) Allow to stand 10 min.
   - (g) Dilute to 500 ml., yielding a final solution with a methemoglobin concentration of 50 mg./100 ml.

This solution may be stored for several weeks at 0-2° C.

Procedure:

1. Place 2 test tubes, each containing 5 ml. guaiacol reagent, in a water bath fitted with a lid and set at 30° C. At the same time place in the bath a tube containing sufficient hydrogen peroxide solution for the tests to be performed.
2. Add 1 ml. serum to be tested to 4 ml. saline. To 2 ml. aliquots diluted serum, add 1 ml. methemoglobin solution to one and 1 ml. water to the other which is to serve as a reagent blank and incubate 10 min. at room temperature.
3. Add to one of the tubes containing guaiacol reagent 0.1 ml. serum-methemoglobin solution and to the other 0.1 ml. serum-water solution. Immediately add to each 1 ml. hydrogen peroxide solution, mix thoroughly, and replace in the covered bath.
4. Incubate 8 min. remove from the bath, and determine the optical density of each at a wavelength of 470 mμ using a water blank to set the instrument to zero optical density.

Subtract the optical density of the reagent blank from that of the test and refer this corrected OD to a calibration curve to obtain serum haptoglobin concentration.

Express the concentration of haptoglobin in terms of its methemoglobin binding capacity.

Although no cuvet size is specified, the conditions described should be satisfactory for use with cuvets supplied with most commercial photometers.

If readings too high or too low are obtained, the test should be repeated, using either a higher or lower dilution of serum.

Calibration curve:

1. Pipet 1 ml. aliquot methemoglobin solution into each of 11 tubes.
2. Add to these respectively increasing amounts of a pooled normal serum free from hemoglobin. The first tube receives 0, the second 0.1, then 0.2, 0.3, 0.4, on to the final tube which receives 1 ml.
3. Adjust the volume in each tube to 2 ml. with saline.
4. Add aliquots of 0.1 ml. each tube to 5 ml. guaiacol and prepare a blank tube containing 0.1 ml. of saline and 5 ml. guaiacol.

Submit these to the procedure described for the unknown beginning with step 3.

Set the spectrophotometer to zero OD with the blank and obtain the OD of each of the tubes.

Plot these readings against the amounts of serum in each reaction tube. The optical density of each successive tube will increase proportionately until a maximum value is reached, after which successive increments of serum will result in no increase in optical density. Thus will be obtained a straight line curve of optical density versus serum amount which will have a sharp inflection point and then level off. The point of inflection and failure to continue to increase indicates that all of the methemoglobin present in the reaction tube has been bound by the haptoglobin in the serum added. This point then represents the equivalent of a serum containing haptoglobin having a binding capacity of 250 mg. methemoglobin/100 ml. The sloping part of the curve relates lower readings to the corresponding haptoglobin contents.

For example, if the point of inflection is reached in the reaction tube containing 0.025 ml. serum, then this OD corresponds to 250 mg./100 ml. binding capacity. The tubes containing smaller amounts of serum then contain 0.005, 0.010, 0.015, and

0.020 ml. serum and correspond, respectively, to 50, 100, 150, and 200 mg./100 ml. methemoglobin binding capacity.

Discussion: Under the conditions chosen here there are a number of contributors to the total oxidation of guaiacol in addition to haptoglobin-methemoglobin complex. These include some nonenzymatic oxidation and the peroxidase activity of the serum itself, which are compensated for by the use of a serum blank, and the peroxidase activity of unbound methemoglobin, which is compensated for by the method of calibration.

The sensitivity of the guaiacol reagent changes with time; therefore it is essential that the calibration curve be repeated at frequent intervals. It is also essential that a covered water bath be used and that readings be made immediately after removal of samples from the bath, as the color formed during the reaction fades significantly on exposure to daylight.

Calibration of haptoglobin content in terms of its methemoglobin binding capacity is chosen since it is possible to measure hemoglobin with reasonable precision, and at present no source of purified haptoglobin exists.

The **mean normal serum haptoglobin content** has been described by a number of authors to be equal to a binding capacity of approximately 100 mg./100 ml.

Laboratory investigation of intravascular hemolysis

Schematic pathway of pigment

Red blood cell → hemoglobin (hemoglobinemia) → haptoglobin → methemoglobin → methemalbumin → hemoglobinuria → methemoglobinuria → hemosiderinuria.

Hemoglobinemia

Color of serum is pink. The test for peroxidase activity of hemoglobin is positive. Spectroscopic examination of plasma reveals free hemoglobin.

Hemoglobin determination in plasma—benzidine method of Crosby-Furth[476a]

Principle: The reaction between benzidine, hydrogen peroxide, and heme-containing pigments produces first a green color, later a blue color, and finally a violet color.

Glassware: Acid cleaned.

Reagents:

1. Benzidine reagent, 1%.

Benzidine base . . .	1 gm.
Glacial acetic acid . .	90 ml.
Distilled water . . .	up to 100 ml.

Keep in refrigerator.

2. Hydrogen peroxide, 1%.
   (a) Prepare by dilution from 30% or 3% hydrogen peroxide. Prepare fresh daily.
3. Standard hemoglobin solution.
   (a) Wash 2 ml. packed red cells 3 times with 0.9% saline.
   (b) Lyse by repeated freezing and thawing, add an equal vol. saline, and centrifuge at high speed to remove ghosts.
   (c) Aspirate the supernatant solution to a graduated tube.
   (d) Determine its hemoglobin concentration by the method in use in the laboratory and dilute with saline to a concentration of 10 gm. Hb/100 ml. This stock standard may be stored frozen for several months. The working standard is prepared by diluting 0.02 ml. stock in 10 ml. saline. This standard contains 20 mg. Hb/100 ml.
4. Diluent solution.
   (a) Dilute 10 ml. glacial acetic acid to 100 ml. with distilled water

Water for reagents must be free of sulfate; test with $BaCL_2$.

Procedure:

1. Withdrawal of blood. Wet a 5 ml. syringe with heparin and expel excess. Make venipuncture in usual manner and permit syringe to fill by venous pressure alone or if necessary use very gentle suction. Mix blood in the syringe by gently inverting several times, transfer to tube, and centrifuge at 1000 r.p.m. for 10 min. Aspirate the upper half only of the plasma layer and recentrifuge. Hemolysis must be avoided.
2. Measure 1 ml. benzidine solution into each of 3 tubes. Add, respectively, 0.02 ml. unknown plasma, 0.02 ml. standard hemoglobin solution (20 mg. Hb/100 ml.), and 0.02 ml. saline.
3. Add 1 ml. peroxide to each tube and mix immediately. Allow to stand 20-30 min. for color development.
4. Add 10 ml. diluent solution to each tube, mix by inversion, and allow to stand 10 min.
5. Determine the optical density (OD) of standard and unknown at 515 mμ, using the reagent blank to set the spectrophotometer to zero OD.

Calculation:

$$\frac{\text{D unknown}}{\text{D standard}} \times 20 = \text{mg. Hb/100 ml. plasma}$$

Comments: The sensitivity of the method as described is such that with most spectrophotometers concentrations of Hb as high as 40 mg./100 ml. may be determined satisfactorily. If OD values greater than 0.6 are obtained, the plasma may be diluted prior to analysis and the result corrected for this dilution. If greater accuracy is desired in the lower range, 0.05 ml. plasma may be used; again the result must be corrected for the difference in the volume of plasma used.

Serum haptoglobin

In the absence of the interfering factors previously discussed, the haptoglobin level is a sensitive test for hemolysis. It is decreased in hemolysis.

Hemoglobinuria

Tests for hemoglobin such as guaiac or benzidine are positive in the absence of red cells in the sediment

Methemalbuminemia

On spectroscopic examination the band is rather faint.

Schumm test:

1. Cover serum or plasma with ether and add 0.1 vol. concentrated ammonium sulfide.

In the presence of methemalbumin a positive Schumm test will show a sharp band at 558 mμ.

Hemosiderinuria

This results from both extravascular and intravascular hemolysis and gives a positive Prussian blue test of the urinary sediment (renal cells and often casts).

Hematologic findings in hemolytic anemia

Peripheral blood:

Anemia: There are decreased hemoglobin and red cell values. The anemia is usually normochromic.

Spherocytosis: Spherocytes occur in both acquired and congenital hemolytic anemia. They represent a prehemolytic state, being easily hemolyzed in hypotonic saline solution (for details, see previous discussion of spherocytes).

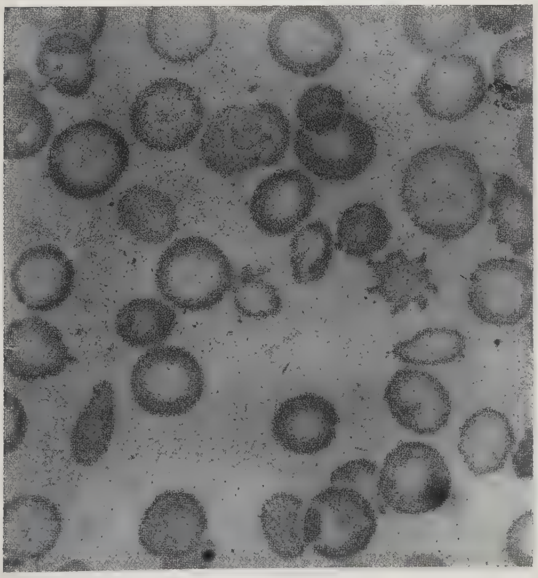

Fig. 425. Blood film of hypochromic anemia showing hypochromia, poikilocytosis, and anisocytosis. (×950.)

Burr cells: These are irregularly shaped erythrocytes and triangular cells which have been described in hemolytic episodes and in uremia.

Schistocytes: These are irregularly fragmented cells.

Heinz bodies: These are seen in preparations stained with supravital dyes and consist of denatured globin (for details, see previous discussion of Heinz bodies).

Reticulocytosis: In hemolytic anemias there is a marked increase in reticulocytes (see previous discussion of reticulocytes). The exception occurs in aplastic crises.

Macrocytosis: This accompanies increased erythropoiesis and may be the result of release of large numbers of reticulocytes.

Siderocytosis: See previous discussion of siderocytes.

Bone marrow findings: There is marked erythroid hyperplasia involving all red cell precursor forms. It is characteristic that the red cell precursors fail to show the morphologic changes which affect the mature red cells and are responsible for the hemolytic process. The myeloid-erythroid ratio is altered so that it may become 1:1 or even reversed, 1:2 or 1:3. Compared with the normal erythropoieses, there is usually a more pronounced increase of proerythroblasts and of erythroblasts so that they are about equal in number to the normoblasts. The hyperplastic erythroid marrow replaces the fatty marrow in the long bones and may expand the flat, short tubular bones. The marrow cavities of these bones become too small to accommodate the growing marrow so that the bony trabeculae as well as the cortices thin out, producing characteristic changes in the x-ray pattern.

Myeloid-erythroid hyperplasia has been classified according to its effectiveness into effective and ineffective erythropoiesis (see discussion of ferrokinetics) as well as into the following 3 types—compensated, decompensated, and dyserythropoietic.

Compensated hyperplasia implies production of a sufficiently increased number of mature red cells which are able to counteract the lytic process so that no anemia develops. If the red cell destruction is of considerable magnitude, an anemia will develop but will not be progressive, representing a stable balance between formation and destruction of red blood cells.

Decompensated erythroid hyperplasia implies that the process falls short of counterbalancing the red blood cell destruction so that immature red blood cells are released into the circulation, such as marrow reticulocytes, nucleated red cells, etc., and a progressive anemia develops.

The dyserythropoietic marrow is quite unable to respond to the lytic process by the required degree of hyperplasia so that a severe progressive anemia develops without any evidence of marrow stimulation and hyperplasia, such as nucleated red cells, marrow reticulocytes, etc.

The bone marrow erythroid hyperplasia is reflected in the peripheral blood by reticulocytosis, macrocytosis, and the appearance of young nucleated forms (erythroblastemia).

Crises

In all hemolytic anemias there occur periods of acute exacerbation which are called

Idiopathic hemolytic anemia

Idiopathic hemolytic anemia

Blood film

Blood film—reticulocytes

Bone marrow

Fig. 426

crises. They are of 2 types—hemolytic and aplastic.

In the hemolytic crisis there occurs a sudden increase in the hemolytic process often associated with further reduction of red cell life span. This crisis is frequently precipitated by an infection.[477]

In the aplastic or aregenerative crisis, in spite of continuing hemolysis, the bone marrow suddenly, but only temporarily, ceases to produce mature erythroid elements. The cause for this failure is unknown, but clinically it is often related to infections or immune mechanisms very similar to the hemolytic crisis. The clinical expression is a rapid precipitous aggravation of the anemia which lacks the usual reticulocytosis and marrow erythroid hyperplasia. The nonerythroid marrow elements are not affected.

In sickle cell anemia a third form of crisis has been described—thrombotic crisis.

Erythrokinetics: As the result of the hemolysis the serum iron is elevated, and this elevation is even more marked in hemolytic diseases in which there is interference with iron utilization. During the recovery period when the hemolytic process declines, the continuing marrow erythroid hyperplasia will produce a fall in the serum iron. Radioiron studies show rapid uptake of serum iron by the hyperplastic bone marrow and increased hemoglobin synthesis. Hemolysis can be increased to about 6 times the normal rate before iron deficiency occurs. The spleen shows increased radioactivity (iron) since most of the hemolysis takes place in this organ. The red cell survival time is, of course, shortened.

Radioiron studies have confirmed the impression that the spleen is always involved in hemolytic disease. Clinically it is usually enlarged. The destruction of red cells in the spleen may be due to several processes. Slowing of the blood stream may lead to sludging, autoagglutination of the red cells, or both. This process leads to metabolic changes in the red cells and enables the spleen to destroy them. That spherocytosis can be considered to be a prehemolytic state has been mentioned. It represents the result of a damaged cell membrane, and these cells, similar to sickle cells and other abnormally-shaped cells, are more easily destroyed. Last, the macrophages, members of the reticuloendothelial system, may engulf damaged or aged erythrocytes (erythrophagocytosis).

Osmotic fragility: Osmotic fragility is increased (see previous discussion).

Autohemolysis: Incubation of sterile defibrinated or oxalated blood at 37° C. shows only minimal spontaneous hemolysis during the first 24 or 48 hr., followed rather rapidly by autohemolysis. In hemolytic anemias the rate of spontaneous lysis is accelerated. This acceleration is due to several factors, among which spherocytosis, action of antibodies, and action of chemicals can be mentioned. The rate of hemolysis can be slowed by the addition of glucose, mannose, and certain nucleosides.

Mechanical fragility: Mechanical fragility is increased (see previous discussion).

HEMOLYTIC ANEMIAS DUE TO INTRACORPUSCULAR DEFECTS

Hereditary spherocytosis (congenital hemolytic jaundice; acholuric jaundice)

This is a hereditary disease transmitted as a mendelian dominant. In its clinical expression it extends from an almost normal carrier stage to a severe hemolytic anemia and from a disease appearing in early infancy and childhood to a condition which may manifest itself for the first time in the later years of life. The homozygous form may not be compatible with life, producing fetal death. Its chronic course is accentuated by more acute episodes and attacks of crises of varying frequency.

The outstanding clinical findings are anemia, jaundice, splenomegaly, and skeletal changes. The hemolytic findings are those of a hemolytic anemia with prominent spherocytosis, anisocytosis, some macrocytosis, and pronounced reticulocytosis.

Hematologic findings

Red blood cells are characterized by a shortened survival time and increased osmotic and autohemolytic fragility, especially after incubation. Whereas most hemolytic anemias show an increased fragility in hypotonic saline solution, it appears that congenital spherocytosis alone shows a decreased resistance to lysolecithin. This is an enzyme normally present in serum which, after having been adsorbed onto the red cells, leads to their destruction in the spleen. Cross survival studies show the previously discussed pattern of an intrinsic defect, the cells of hereditary spherocytosis disappearing rapidly in a normal recipient.

Pathophysiology of red blood cells

Splenectomy is clinically a curative procedure in patients suffering from hereditary spherocytosis, but it does not affect the red blood cell abnormality. The exact nature of the intrinsic defect is not known. Loehr described several enzymatic defects which produce abnormalities of the intracellular glycolytic metabolism. Such a defect can be proved by the incubation of red cells of hereditary spherocytosis with P^{32}. The P^{32} absorption is normal, but its utilization is abnormal. More P^{32} is used for the formation of inorganic phosphates and much less is incorporated into 2-3-diglycerophosphate and adenosine triphosphate. This defect can be corrected by the addition of glucose and nucleosides. It has also been shown that the cells of hereditary spherocytosis contain a slightly diminished amount of potassium.[478] It is possible that the metabolic defects described are related to changes in the red cell membrane which has been reported to contain a lessened amount of lipid. Not all cases of hereditary spherocytosis may have the same type of intrinsic defect. Allison[479] showed that the red cells of hereditary spherocytosis show a defect in the synthesis of phosphatidyl ethanolamine so that lysogenic compounds (lysophosphatidyl ethanolamine) accumulate within the red cells.

Anemia: The hemoglobin levels vary considerably from case to case and sink rapidly during a crisis. The peripheral blood film shows anisocytosis and Cabot rings and may contain siderocytes and Howell-Jolly bodies. The latter two are especially frequent after splenectomy. Supravital stains show numerous reticulocytes, many of which may contain only one single blue dot.

Leukocytes: The white blood cell count is not pathologic. During a hemolytic crisis it may increase and show a shift to the left, whereas in an aplastic crisis it may decline to leukopenic levels.

Bone marrow: The picture is that of erythroid hyperplasia and reticulocytosis. The latter, according to Rohr,[480] is characteristically less in the bone marrow than in the peripheral blood in cases of hereditary spherocytosis.

Plasma: Increase in nonconjugated indirect-reacting bilirubin, hence jaundice.

Nonhematologic findings

Urine: Increase in urobilinogen and urobilin.

Liver: Pigment stones in the gallbladder.

Spleen: Splenomegaly.

Skeletal system: Tower-head formation is often associated with deformities of the fingers and vertebrae. Bone marrow hyperplasia leads to widening of bones and to abnormal spacing of teeth and radiologic appearance of rarefaction. There is a sunray effect on x-ray films of the skull.

Eyes: Mongolian fold.

Treatment

Splenectomy (accessory spleens?) is the treatment of choice. The basic defect is not influenced, but the site of hemolysis is removed.

Enzyme-deficient hemolytic anemias

In this classification fall the hemolytic anemias produced by the action of certain drugs (primaquine, sulfanilamide, acetanilid, phenacitin, and other aniline derivatives, naphthalene, phenylhydrazine, Furadantin) and by certain legumes (fava bean and peas) in certain susceptible individuals. In most patients these substances do not produce a hemolytic anemia, but in a few they do. Such sensitivity was first noticed in American Negroes treated with primaquine for malaria. The common denominator of all these anemias is a congenital defect in the aerobic glycolytic pathway, a deficiency in glucose 6-phosphate dehydrogenase (G6-PD) activity. This defect is inherited as a sex-linked gene of intermediate dominance. Loehr has shown that this deficiency leads to a fall in the reduced glutathione, in triphosphopyridine nucleotide (TPN), and in diphosphopyridine nucleotide (DPN). These enzyme-deficient cells have a normal survival time, and hemolysis occurs only if they come in contact with one of the substances just mentioned. These substances apparently interact with oxyhemoglobin to form hydrogen peroxide (H_2O_2), which in normal cells is destroyed in the presence of reduced glutathione and glutathione peroxidase. In normal cells reduced glutathione is rapidly regenerated from the oxidized glutathione. In the face of G6-PD deficiency TPNH formation is inadequate, and glutathione is inadequately reduced so that H_2O_2 is not decomposed, and hemoglobin is subjected to oxidation and decomposition with the result of Heinz body formation and hemolysis.

The destruction mainly involves older cells which normally have a reduced glutathione, adenosine triphosphate (ATP), and DPN complement so that even in the face of continuing administration of any of the aforementioned toxic substances, the hemolysis ceases for a period of several weeks until the young cells, which enter the circulation with a normal complement of reduced glutathione, reach about the sixtieth day of their lives.

The hemolysis produced by the fava bean is not adequately explained as yet, though it may be related to the action of an anthraquinone derivative.

The hemolysis, which apparently is due to an intrinsic corpuscular defect, is intravascular in type and leads to hemoglobinuria but usually not to other manifestations of intravascular hemolysis.

Laboratory diagnosis of primaquine type of hemolytic anemia

The diagnosis of the primaquine type of hemolytic anemia and of the sensitivity of patients to these drugs prior to their administration can be established by several tests.

Beutler[481] found that in vitro drug-sensitive erythrocytes form small scattered Heinz bodies more readily and in greater number than do nonsensitive erythrocytes when they are incubated with acetylphenylhydrazine. The nonsensitive erythrocytes form only a few marginal somewhat larger Heinz bodies. Later Beutler[482] described a less subjective test based on the fact that in sensitive red cells the reduced glutathione level is lower than in nonsensitive cells. The **reduced glutathione stability test** consists of incubating blood samples with acetylphenylhydrazine and measuring the reduced glutathione level before and after incubation.

The latest method of investigation is the determination of glucose 6-phosphate dehydrogenase level. This level is measured indirectly by measuring the rate of TPNH formation. This reaction is based on the following reaction which is catalyzed by glucose 6-phosphate dehydrogenase.

Glucose 6-phosphate + TPN → 6-Phosphogluconate + TPNH

It was also found that as TPNH is formed it reduces brilliant cresyl blue dye to a colorless form. The rate at which the color of the dye disappears can be followed visually and is proportional to the glucose 6-dehydrogenase content of the red cells. A colorimeter is not required. This procedure appears to lend itself to mass screening. The dye has been stabilized and a simple test perfected[483] wherein 0.3M TRIS buffer and a red cell hemolysate are added to a vial containing the dye and a stabilizer.

Pathophysiology

Danon[484] examined the glucose 6-phosphate dehydrogenase-deficient erythrocyte with the electron microscope and found that the enzyme-deficient cells have a smooth cell membrane, whereas control cells show a granular pattern. In normal peripheral blood the granular pattern is characteristic of young cells and is present in 70% or more of all cells. The smooth pattern, on the other hand, in normal blood is characteristic of old cells. Electron microscopic examination of drug-sensitive blood shows a reversal of the normal ratio so that smooth cells predominate (60% or more). This morphologic change alone cannot be the etiologic factor of enzyme-deficient hemolytic anemias, as these cells, when not exposed to drugs, etc., have a normal survival time.[485, 486]

The drug-sensitive cells lack an activator of G6-PD which is present in the stroma of normal cells.

Waller[487] showed that the erythrocytes of some patients are almost devoid of glucose 6-phosphate dehydrogenase, whereas Dacie[488] was able to show complete arrest of glycolysis in other cases.

Congenital Heinz body anemia

Gasser[489] described congenital Heinz body anemia in premature infants who developed hemolytic jaundice in the first few days of life. Later Veradi[490] found a similar disease in full-term children. The association of Heinz body and methemoglobin formation has been discussed previously. As methemoglobinemia frequently follows drinking of nitrite-rich well water, it has been suggested that intestinal bacterial nitrite formation may be related to this type of anemia. Normal erythrocytes are rich in the enzyme catalase which splits H_2O_2 into oxygen and water, whereas the erythrocytes of infants contain a diminished amount of this enzyme. There is experimental evidence available that lowered catalase activity is associated with increased tendency to Heinz body formation. This concept of a congenital absence or diminution of this enzyme is supported by the findings in those enzymatic deficient anemias in which Heinz bodies are seen when the anemia follows the ingestion of aniline dyes, sulfonamide drugs, naphthalene, etc. There is also experimental evidence which links hyposplenism (splenic agenesis and splenectomy) to Heinz body formation.

Hereditary (congenital) nonspherocytic hemolytic anemia[491]

This classification includes a number of chronic hemolytic anemias which are due to an intrinsic enzymatic corpuscular defect. They vary in expression of the hemolytic process, showing variations in red cell morphology, osmotic fragility, and clinical course. They are united by such features as absence of spherocytosis and thus fail to show increased fragility, and though they are congenital, a good family history is often lacking. They are most commonly found in subjects of British and Northern European descent. Splenectomy is not followed by clinical improvement.

Selvyn and Dacie[492] differentiate 2 types which cannot be distinguished clinically but which show changes in autohemolytic behavior.

Type I
Normal autohemolysis of whole blood decreased by the addition of glucose but not corrected up to the normal response

Type II

Increased autohemolysis of whole blood not corrected by the addition of glucose

Hematologic features

The morphologic picture varies considerably from case to case, but slight anisocytosis is evidenced by the presence of macrocytes, normocytes, occasional elliptocytes, and target cells. Slight reticulocytosis and polychromasia may be seen. The osmotic fragility before incubation is normal in both types but is increased in type II after incubation.

Other types of congenital hemolytic anemia

Such anemias have been described in congenital porphyria[493] (erythropoietic porphyria) in which the cells fluoresce under ultraviolet light since they contain an increased amount of free erythrocyte protoporphyrin (fluorescytes).

Normal erythrocytes contain a small amount of free porphyrin (erythrocyte protoporphyrin [E.P.]).[494, 495] In cases of impaired hemoglobinization, there occurs an increase in E.P., indicating inadequate utilization of protoporphyrins in the process of hemoglobin synthesis. An increase of E.P. is seen in iron-deficiency anemia and in regenerative hemolytic anemias; normal values are found in pyridoxine deficiency and in pernicious anemia (see discussion of porphyrins).

Thalassemia

Thalassemia is a hemolytic anemia associated with an inherited intracorpuscular defect of erythrocytes. First differentiated by Cooley and Lee,[496] it has often been referred to as Cooley's anemia. This syndrome has also been designated Mediterranean anemia or Mediterranean disease. The latter designation has been applied chiefly because the syndrome has occurred most frequently in people of Mediterranean stock, with Italians predominating. Although scattered cases had been described in non-Mediterranean stock, it was not until Minnich and co-workers[497] reported 32 cases in Thailand that any considerable number had been collected outside of this group. In subsequent studies, most of these cases were found to be a combination of Mediterranean-E hemoglobin disease rather than pure thalassemia.[498] It is quite generally agreed today that the syndrome is due to an inherited characteristic of the erythrocyte as a mendelian dominant. Two major subdivisons are recognized: (1) the symptomatic disease form, thalassemia major, and (2) an asymptomatic form, thalassemia minor. Thalassemia major is the homozygous disease form with a double dose of the gene for the syndrome, whereas thalassemia minor is the heterozygous trait form, having only one gene for Mediterranean disease. In addition to these major divisions, studies of electrophoresis and alkali denaturation have revealed combinations of thalassemia and molecular disease of hemoglobin. Examples of such combinations are sickle cell-thalassemia disease, thalassemia-C disease, and thalassemia-E disease (see discussion of molecular disease of hemoglobin, pp. 1280ff). The combination of sickle cell-thalassemia is sometimes referred to as microdepranocytosis.

Other combinations are with hemoglobin-G, hemoglobin-H, and Bart's hemoglobin. When hemoglobin-E is present, there is usually no other hemoglobin detectable by electrophoresis. The presence of hemoglobin-H is revealed by intraerythrocytic inclusions which can be seen with supravital stain. It is possible that the thalassemia gene potentiates the abnormal hemoglobin genes. Abnormal hemoglobins are inherited by a single gene.

Thalassemia major

In the disease form anemia is a striking feature, varying in intensity from patient to patient, but often of sufficient severity to cause symptoms. An outstanding feature of the disease is the x-ray appearance of the skull which shows perpendicular striations suggesting hair standing on end. Involvement of other bony structures may be present, and in the hands it takes on a mosaic pattern on x-ray examination. These changes are the result of bone marrow hyperplasia. They also lead to characteristic facial expressions and changes such as a round skull, a broad nose with an indented bridge, and a mongolian type of inner canthal folds.

Splenomegaly may occur and at times reaches fairly high proportions. The hemolytic crises are often attended by febrile periods, but jaundice is infrequent. As a result of the anemia, debility, and perhaps a lessened resistance, intercurrent infections are fairly frequent, and life expectancy is considerably reduced so that many of these patients do not live beyond childhood.

Hematologic findings

The blood picture in the disease form shows an anemia of variable degree, ranging from 1,000,000 up to 3,500,000 red cells/c.mm.

There is a pronounced lowering of the hemoglobin and hematocrit values, with a resultant hypochromic microcytic anemia. The blood spread not only reflects this hypochromasia and microcytosis but also shows marked poikilocytosis and anisocytosis. During and shortly following a hemolytic crisis, nucleated erythrocytes are commonly seen in the blood spreads, and Howell-Jolly bodies may be present. Target cells in varying numbers are so regularly encountered that their presence in a blood spread should always suggest thalassemia as a possible diagnosis. These cases are more common in hemoglobin-C disease. The target cells (leptocytes or platycytes) are hypochromatic and thin. They may break easily and may give rise to schistocytes. The end result of all these morphologic changes is a picture of markedly deformed red cells frequently represented by hemoglobin rings only. The red cell diameter may vary from 2-10μ. Electron microscopic pictures of the red cells show iron granules or ferritin and abnormal hemoglobin derivatives deposited within the cytoplasm. These changes are not seen in thalassemia minor and indicate poor iron utilization of thalassemic red cells.

Reticulocytes are often increased. There are no significant changes in the platelets. The leukocyte count may be considerably elevated during a period of hemolytic crisis. The bone marrow is usually hyperplastic, displaying a normoblastic hyperplasia which is not a specific characteristic enabling a diagnosis of the disease. Nests of foamy reticulum cells can be found at times.

Fragility studies of the erythrocytes show either a normal osmotic fragility or may show an increased resistance in hypotonic saline. This increase is partially explained by the flattening and thinning of the red blood cells in thalassemia. It is an important differential point in cases in which the blood picture because of its anisocytosis resembles hereditary spherocytosis. On the other hand, the mechanical fragility is increased.

Red cell survival studies reveal a diminished survival time in some cases and a normal survival in others.[499] The observations of Singer et al.[500] that thalassemia major displays a considerable increase in hemoglobin-F have been verified by many observers.

The hemoglobin in thalassemia is thus a mixture of hemoglobin-A and hemoglobin-F. The F component is similar to fetal hemoglobin and may vary in amount from 10-80% or more. The amount is not related to the severity of the disease, but the presence of hemoglobin-F is one of the characteristics of all thalassemias. With starch block electrophoresis another hemoglobin can be identified which is normally not present at birth. It is seen in low concentration in other anemias, but is present in high concentrations in thalassemia minor. This hemoglobin is labeled hemoglobin-A_2. In lower concentrations it is also found in thalassemia major. At the age of 3 mo., up to 3% may be found in peripheral blood; in various anemias the level may rise to 4%; in thalassemia it may vary from 1-9%, whereas in thalassemia minor it rises to 13%. There is no relationship between hemoglobin-A_2 and hemoglobin-F except that when hemoglobin-F concentrations are high hemoglobin-A_2 concentration is usually low. The finding of hemoglobin-A_2 is valuable in the diagnosis of the carrier state (heterozygous form).

Nonhematologic findings

Serum findings: Nonconjugated bilirubin is increased. Serum iron is elevated, and iron binding capacity is low. The latter feature is an important point in differentiating thalassemia from severe iron-deficiency anemia.

Urinary findings: Urobilinogen is increased; amino acid uria has been described. The latter may be an expression of the hemolytic process or may be due to kidney or liver damage.

Thalassemia minor

In thalassemia minor all signs and symptoms of thalassemia major may be present but to a lesser and markedly variable degree. Despite apparently similar genetic background (heterozygosity for the thalassemia gene), these patients show extreme variations in symptoms so that etiologically gene interaction or protective mechanisms must be considered. The fetal hemoglobin may vary from 2-12% or may be absent. As pointed out previously, in most heterozygous patients hemoglobin-A_2 is increased diagnostically.

Thalassemia intermedia

Thalassemia intermedia[501, 502] is a clinical term denoting clinical and hematologic features ranging between those observed in thalassemia minor and thalassemia major. These patients usually include young adults or adults who more or less show the features of thalassemia major. They differ from thalassemia major by the very fact that the homozygous form of Cooley's anemia usually leads to death in early childhood. Genetic studies were made in some of the reported cases, and it could be shown that both parents had thalassemia minor. The children therefore had to be considered to be suffering from the homozygous form of Cooley's anemia. The electrophoretic hemoglobin pattern shows the presence of fetal hemoglobin and hemoglobin-A_2.

Pathophysiology of thalassemia

As previously mentioned, Heilmeyer classifies thalassemia in the sideroachrestic anemias since the thalassemia gene interferes with the heme synthesis. There is also evidence that thalassemia is the result of a biochemical change in the hemoglobin molecule which may be the result of mutations which affect the alpha or beta hemoglobin polypeptides. The thalassemia gene apparently suppresses beta polypeptide production so that gamma polypeptide production (fetal hemoglobin) is free to assert itself (see discussion of abnormal hemoglobin).

Last, hemoglobin metabolism[503] studies suggest not only the defect in hemoglobin synthesis but also an abnormality of erythrocyte production.

In the combinations of thalassemia and sickle cell hemoglobin-C or hemoglobin-E, the clinical and blood pictures appear to have a position intermediate between thalassemia disease and thalassemia trait. Although sickling is not present in thalassemia alone, sickling of the red cells is demonstrable when it combines with the sickle form. Electrophoretic studies in these combinations demonstrate the abnormal hemoglobin-S, hemoglobin-C, or hemoglobin-E, as well as hemoglobin-F. However, attention is again called to the fact that hemoglobin-F has a mobility approximating that of hemoglobin-A and cannot be readily demonstrated by paper electrophoresis.

Paroxysmal nocturnal hemoglobinuria

Paroxysmal nocturnal hemoglobinuria,[508, 509] often referred to as the Marchiafava-Micheli syndrome, is associated with a chronic hemolytic anemia with acute paroxysms of hemolytic crises occurring at night. These crises are of sufficient degree to result in hemoglobinuria. Although the red cell is the predominant hemopoietic element involved, the white cells and platelets may also be affected. Crosby[504] has presented a magnificent review of this syndrome, together with many of his original observations. He concludes that paroxysmal nocturnal hemoglobinuria is an acquired disease of the hemopoietic system in which abnormal red cells, white cells, and platelets are then susceptible to some normal plasma factor which is believed to be properdin.[505] This serum euglobulin is distinct from complement and the components of the clotting system but requires complement and magnesium ion for its activity. Crosby calls attention to the fact that hemolytic crises occur when the patient is asleep (whether at night or day), and that during this period changes in the balance of an inhibitor-hemolysin system may account for the crises. Other investigators have felt that changes of pH are produced by retention of CO_2 during sleep; this observation forms the basis of the Ham[506] acidification test and its modifications.

In addition to the anemia, these patients develop leukopenia which may become chronic and perhaps contributes to the increased susceptibility to infection that these patients show.

Thrombocytopenia is generally not marked, and purpura is uncommon. However, agglutination of platelets in this disease accounts for the vascular thromboses seen in paroxysmal nocturnal hemoglobinuria. There appears to be some evidence of a vicious cycle of competition between members of the coagulation mechanism (especially thrombin) and the factors involved in paroxysmal nocturnal hemoglobinuria. Dicumarol has had some beneficial effect in protecting these patients against thrombotic episodes and perhaps the development of anemia. Heparin, on the other hand, causes increased hemolysis.

We are thus confronted with a rather rare disease characterized by pancytopenia caused by at least 2 factors: (1) the plasma factor and (2) an intraerythrocytic factor.

Plasma factor

There is some doubt whether the complement-properdin-magnesium system is involved (or is the only plasma system involved), as Crosby[507] found that a thrombin-plasma factor system was linked to the hemolytic process, the plasma factors being in the nature of antibodies.

Intraerythrocytic factor

Paroxysmal nocturnal hemoglobinuria is essentially due to an intraerythrocytic defect. Crosby[507] proved the existence of an abnormal ratio of erythrocytic fatty acids as well as an associated stromal defect. The latter can also be seen by electronmicroscopy but has been claimed to be artifactual by some observers. Acetylcholinesterase activity is subnormal, but a similar defect is exhibited by other diseases which do not have a hemolytic component. The cause of paroxysmal nocturnal hemoglobinuria is still not known. During an attack, both the mature peripheral red cells and the immature marrow erythroblastic cells hemolyze. The marrow responds only poorly and inadequately to the hemolytic red cell destruction.

Laboratory tests

Urine: Dark, especially notable after sleep.

Plasma: Usually darker in the morning than in the afternoon and evening.

Autohemolysis: Rapid at 37° C.

Ham test (acid serum test):

1. Acidify 0.5 ml. serum by adding 0.05 ml. 2.2N HCl acid.
2. Control—0.5 ml. unacidified serum.
3. Add 1 drop 50% suspension of patient's washed cells to each serum, incubate at 37° C. for 1 hr. and then centrifuge.

If the cells are from a case of paroxysmal nocturnal hemoglobinuria, marked hemolysis occurs after 15 min.

Thrombin test (Crosby):

1. Prepare an acidified red cell and serum mixture and control as for the acid serum test.
2. To 1 ml. each mixture add 100 units bovine thrombin dissolved in 0.1 ml. saline.
3. Incubate both tubes at 37° C. for 15 min.

If the cells are from a case of paroxysmal nocturnal hemoglobinuria, more hemolysis occurs in the presence of thrombin.

Blood picture: This has been described previously. Anemia and reticulocytosis are only slight.

Paroxysmal cold hemoglobinuria

This condition is found in syphilis and is often acutely brought on by sudden chilling of the body surface. The urine is diagnostic; if taken directly after or during the attack, color varies from brown red to black; acid reaction; specific gravity depends on kidney function and water balance; on boiling, a brown coagulum of albumin develops; hyaline casts are present; spectroscopically, bands of hemoglobin and methemoglobin; there are no red cells in the urine; urine contains urobilin.

During the attack the following **Donath-Landsteiner autohemolysis phenomenon** may be found:

1. Place some blood in a test tube.
2. Chill to 5° C. for 10 min. Hemolysis will occur.

Normal blood will show no such hemolysis.

This test is based upon the fact that in this disease a special hemolytic substance has been liberated into the blood stream. In the blood picture there are leukopenia, hypochromia, and poikilocytosis during the attack.

Familial hemolytic anemia with erythrocyte inclusion bodies and defect in pigment metabolism

Schmid et al.[510] and Scott et al.[511] in 1959 and 1960 described several cases of a severe congenital hemolytic anemia characterized by Heinz body-like intraerythrocytic inclusions. These were also found in reticulocytes and in a few normoblasts. The erythrocytes contained siderocytic granules, basophilic stippling, and rodlike structures. In all reported cases splenectomy had been performed. The urine contained a dark brown pigment believed to be mesobilifuscin. Scott's patient also showed evidence of an abnormal hemoglobin, bringing to mind the hemolytic anemia occasionally associated with hemoglobin-H.

Molecular diseases of hemoglobin

Pauling's[512] discovery of the differences in electrophoretic mobility of normal and sickle cell hemoglobin has opened a rapidly growing field in the investigation of hemoglobin. The basic concept of this work is that hemoglobin exists in various molecular structures that differ from that of normal hemoglobin. These differences can be elucidated by electrophoresis, as well as by other methods such as gel formation,[513] tactoid formation in phase microscopy,[513-515] and alkali denaturation.[516] The technic of paper electrophoresis for studying proteins, including hemoglobin,[517, 518] has supplemented the much more complicated and expensive Tiselius apparatus and has opened the way to large-scale investigation of diseases associated with hemoglobin molecular disease.

The **nomenclature**[519] **of the various types of hemoglobin** now described on the basis of electrophoretic patterns are as follows: (1) Normal adult hemoglobin or hemoglobin-*A*, (2) normal fetal hemoglobin or hemoglobin-*F*,[516] (3) sickle cell hemoglobin or hemoglobin-*S*,[520] (4) hemoglobin-*C*,[520-522] (5) hemoglobin-*D*,[520, 523] and (6) hemoglobin-*E*.[524]

Hemoglobin-E was identified in 1954. Since then the following hemoglobins have been described: *G, H, I, M, J, K, N, O, L, P,* and *Q*. There are still others as yet not designated by letters, such as Lepore hemoglobin, Bart's hemoglobin, and others.[525, 526]

With the exception of hemoglobin-M, all abnormal hemoglobins show normal oxyhemoglobin dissociation curves.

Table 250. *Distribution of various types of hemoglobin*

	Hemoglobin type					
	A	*S*	*C*	*D*	*E*	*F*
Normal newborn	15-50%	–	–	–	–	50-85%
Normal child up to age 2½ yr.	97-100%	–	–	–	–	Up to 3%
Normal adult	98.4-100%	–	–	–	–	Trace
Sickle cell trait	55-76%	24-45%	–	–	–	Trace
Sickle cell disease	–	75-100%	–	–	–	0-25%
Hemoglobin-C disease	–	–	100%	–	–	Trace
Hemoglobin-C trait	60-75%	–	25-40%	–	–	Trace
Sickle-C disease	–	33-50%	50-67%	–	–	Less than 2%
Thalassemia-C disease*	25%	–	75%	–	–	Trace
Hemoglobin-D trait	51-65%	–	–	35-49%	–	–
Sickle-D disease	–	?	–	?	–	?
Thalassemia minor	90-100%	–	–	–	–	0-10%
Thalassemia major	0-60%	–	–	–	–	40-100%
Sickle-thalassemia disease	18-33%	67-82%	–	–	–	1-17%
Hemoglobin-E trait†	++++	–	–	–	+	–
Hemoglobin-E disease†	–	–	–	–	94-98%	2-6%
Thalassemia-E disease†	–	–	–	–	60-80%	20-40%

*Singer, K., et al.: Blood **9**:1032, 1954; Zuelzer, W. W., and Kaplan, E.: Blood **9**:1047, 1954.
†Chernoff, A. I., et al.: Proc. Cent. Soc. Clin. Res. **27**:26, 1954.

These hemoglobin types are inherited. Neel[527, 528] has reported the inheritance pattern of the sickling phenomenon in 75 kindreds. He maintains that this phenomenon is "due to a gene which in single dose (heterozygous condition) produces only the sickle cell trait, and in double dose (homozygous condition) sickle cell disease."* Translated into terms of abnormal hemoglobins, patients with sickle cell trait are represented by an S-A gene pattern, whereas those with sickle cell disease have an S-S pattern. The same principle applies to other combinations of abnormal hemoglobins. In the trait, quantitative electrophoretic studies show small amounts of abnormal hemoglobin in combination with relatively large amounts of normal hemoglobin. On the other hand, the disease syndrome reveals almost 100% abnormal hemoglobin. Motulsky and co-workers[529] report the following typical distribution of hemoglobins in various syndromes observed by them or collected from the literature. Table 250 is a modification, based on observations made subsequent to their report.

The electrophoretic mobilities of the various hemoglobins result in the following order: closest to the starting point is B_2, then follow C, E, (A_2), O, S, (D), L, (P), G, Q, A_1, A_3, (M, F), K, J, N, H and (I). This order applies to paper electrophoresis with veronal buffer pH 8.6. Parentheses () indicate that the hemoglobins cannot be separated from each other by this particular method. Such separation may be achieved by modified electrophoresis technics.

The mobility of hemoglobin-F so closely approaches the speed of hemoglobin-A that these two components are generally inseparable in the paper electrophoresis technic, although Smith and Conley[530] claim such separation is possible. In the Tiselius apparatus, the F component can be readily identified. In most clinical studies, the alkali denaturation technic[516] has been the method of choice for demonstrating hemoglobin-F. Hemoglobin-D has the same mobility as hemoglobin-S and cannot be separated by electrophoresis. Differences in solubility[520] have been used as a means of distinguishing these two components.

The presence of these various abnormal hemoglobins may or may not result in symptoms. In general, patients with a homozygous pattern and high percentages of abnormal hemoglobin show marked symptoms. Hemolytic crises with resultant anemia are prominent features. Associated with these crises are severe abdominal pain, fever, headache, hematuria, pallor, tachycardia, and dyspnea. Abdominal pain may be so severe as to suggest a surgical condition of the abdomen, and patients in this category have been mistakenly operated upon as emergency cases. Jaundice, as a result of excessive red blood cell destruction, is quite common, and hematuria is found occasionally. Vascular thromboses may result in a multiplicity of symptoms with the brain a fairly common site for such episodes. On physical examination the degree of pallor is proportionate to the anemia. Jaundice may be

*From Neel, J. V.: Blood **7**:467, 1952.

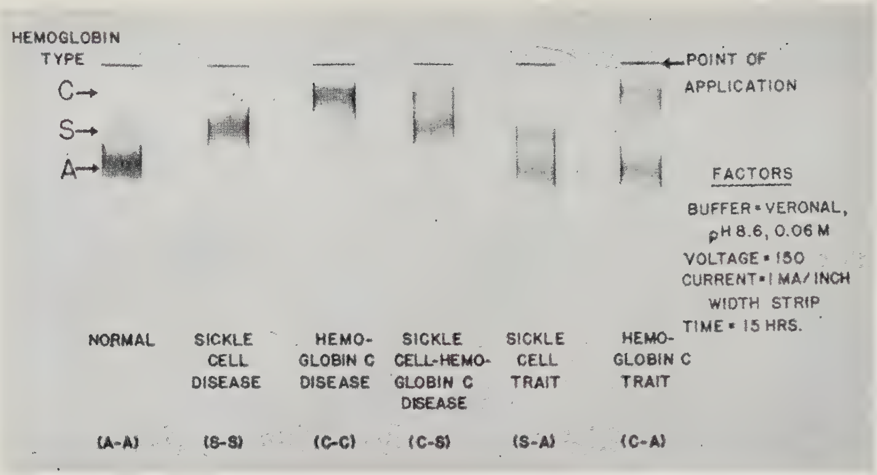

Fig. 427. Electrophoretic determination of hemoglobin types. Separation of hemoglobins by filter paper electrophoresis. (From Weinstein, I. M., Spurling, C. L., Klein, H., and Necheles, T. F.: Blood **9**:1157, 1954.)

present. Splenomegaly and sometimes hepatomegaly are quite common. In the heterozygous state, abnormal clinical findings are absent, and the patient's history is essentially negative. In combined states, such as sickle cell-hemoglobin-C disease, the clinical picture is generally intermediate in severity between the homozygous and heterozygous conditions. Although the picture is generally milder in such combinations, Smith and Conley[530] call attention to 2 patients in whom hemolytic crises were sufficiently severe to produce jaundice and profound anemia.

Just as the clinical pattern seems to follow the types of hemoglobin present, there also appears to be some parallelism in the hematologic studies. In the **homozygous** states, generally an anemia of varying degree occurs and may be quite profound. The stained blood spreads show numerous target cells, ranging from 60 to almost 100% of the red blood cells. During crises anisocytosis (chiefly microcytosis) and poikilocytosis are marked, and nucleated erythrocytes are common. Polychromasia is often seen. In those patients with sickle cell disease, sickled erythrocytes may rarely be seen in the blood spread. Osmotic fragility studies reveal an increased resistance. Mechanical fragility tends to be normal in an oxygen atmosphere but is increased in an atmosphere saturated with carbon dioxide. Reticulocytes are often increased, especially during or shortly after a hemolytic crisis. Siderocytes, which are iron-staining bodies within the erythrocytes, tend to be numerous.[531] Sickling is demonstrated only in patients with hemoglobin-S and may approximate 100% in some instances. In this respect, it is important to point out that sickling of such proportion occurs only in the homozygous S state. Homozygous C and E and thalassemia are not accompanied by sickling phenomenon. When these are combined with sickling such as sickle cell–hemoglobin-C disease, sickling will occur but to a lesser degree than in homozygous S.

Combinations of sickle cell and other abnormal hemoglobins, such as sickle cell–hemoglobin-C disease, show intermediate hematologic values. Kaplan, Zuelzer, and Neel[531] were particularly impressed with the markedly high target cell incidence in sickle cell–hemoglobin-C disease. Apparently variations in hematologic abnormalities may show the same wide variations that the clinical pictures display, ranging from relatively mild to very severe.

In the **heterozygous** or **trait** states hematologic studies reveal minimal deviations from normal. Anemia is not present. Target cells occur much more frequently than in normal people, but the percentage of such cells rarely exceeds 20%. Osmotic fragility tends to be normal or occasionally decreased, and mechanical fragility is generally normal or only slightly affected in CO_2. Siderocytes are absent or rare. Sickling in wet preparations is minimal, rarely exceeding 20% in subjects with hemoglobin-S.

From a clinical standpoint, the relationship of hemoglobin-F concentration to disease is not quite as clear-cut as with the other abnormal hemoglobins. Its high concentration in newborn infants (almost 100%) is not implicated in any disease process.

In the embryo a precursor form of hemoglobin-F may be present. In the fetus, hemoglobin-F may be carried by a red cell population different from the one carrying hemoglobin-A. In the first few months of extrauterine life, the percentage of fetal hemoglobin falls to about 10%; after 12 mo. it reaches the adult level of about 1%. It may be recapitulated that the presence of hemoglobin-F in the mother's circulation can be used as evidence of bleeding of the fetus into the maternal circulation (see discussion of hypochromic anemias).

Hemoglobin-F differs from adult hemoglobin in the following properties: (1) x-ray diffraction shows molecular differences between hemoglobin-A and hemoglobin-F, (2) fetal reduced hemoglobin is more soluble than adult reduced hemoglobin, (3) the amino acid composition of the globin moiety of fetal hemoglobin differs from the composition of adult hemoglobin, (4) the oxygen dissociation curve shows a higher affinity and loading capacity than adult hemoglobin and, (5) hemoglobin-F is easier oxidized than hemoglobin-A.

Singer and co-workers[516] originally demonstrated its association with sickle cell disease in which values ranging from 2-23.9% were found. Since this original publication, denaturation studies have taken on a pattern. Sickle cell–hemoglobin-C disease and sickle cell–thalassemia disease are both associated with high values for fetal hemoglobin. Thalassemia major is also associated with increased hemoglobin-F values. Mild elevation of hemoglobin-F has been noted in hemoglobin-E disease. When thalassemia is combined with other abnormal hemoglobins (e.g., thalassemia hemoglobin-E disease), fetal hemoglobin values are elevated. In the trait states of hemoglobin-S or thalassemia minor, the values are normal. Increased amounts of hemoglobin-F have been noted in some miscellaneous conditions, such as hereditary spherocytosis, chronic aregenerative anemia, untreated pernicious anemia, myelophthisic anemia, and some leukemia conditions often associated with extramedullary hematopoiesis.

Variations of hemoglobin-F have been described which are sensitive to alkali denaturation (Bart's hemoglobin and others).

Biochemistry of abnormal hemoglobins

In any given species the composition of the protein moiety of hemoglobin is genetically controlled so that no changes occur in its amino acid composition from generation to generation. On the other hand, if mutations occur (sometimes silent), the altered gene may produce changes in the amino acid sequence. The abnormal hemoglobins[531b] vary in their globin composition, whereas the heme component is the same for all hemoglobins. The abnormal hemoglobins have been designated by capital letters, as already stated, more or less in the order of their discovery. Two allelic genes control the synthesis of hemoglobin-A, hemoglobin-S, and hemoglobin-C, the latter 2 representing mutant forms of hemoglobin-A. Whether hemoglobin-F[531c] is also controlled by 2 allelic genes or is the result of environmental factors acting on a single cell capable of producing either hemoglobin-A or hemoglobin-F has not been decided as yet.

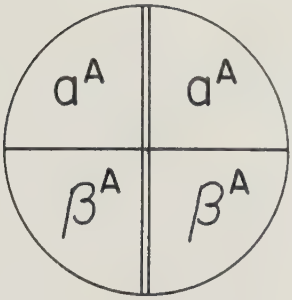

Fig. 428. Globin pattern of hemoglobin.

The globin moiety of hemoglobin can be visualized as a combination of 2 half-molecules, each half-molecule being a mirror image of the other. Each half-molecule contains 2 different polypeptide chains, an alpha chain and a beta chain, so that the entire molecule contains 2 alpha and 2 beta chains and can, in the case of hemoglobin-A, be represented by the formula $\text{alpha}_2{}^A/\text{beta}_2{}^A$.

Ingram[531a] by finger printing of hemoglobins found that amino acid changes in these polypeptide chains characterize each abnormal hemoglobin. He hydrolyzed or digested the protein into polypeptides and then separated them into individual peptides and amino acids by electrophoretic-chromatographic or chemical methods. Further electrophoresis in the presence of a detergent allowed allocation of the amino acids to one or the other of the chains. The composition of these polypeptide chains is controlled by 2 genes, one gene for each chain. These genes are not linked and are probably situated on separated loci. Any mutation in one or the other genes will result in changes in the amino acid composition of the chain.

Hemoglobin-A contains glutamic acid in

the beta chain, whereas in hemoglobin-S the same position is occupied by valine, and in hemoglobin-C it is occupied by lysine. Fetal hemoglobin contains a different arrangement of amino acids called the gamma chain. In each half-molecule it also contains an alpha chain as it occurs in hemoglobin-A. Hemoglobin-F is therefore represented by the formula $\text{alpha}_2{}^{A}$ $\text{gamma}_2{}^{F}$. Changes in the alpha chain have been found in hemoglobin-I. Hemoglobin-A_2 is characterized by a delta chain.

Investigation of abnormal hemoglobins

Identification and estimation of fetal hemoglobin—Chernoff-Singer

Alkali denaturation[534, 535]

Preparation of hemoglobin solution:

1. Collect approximately 5 ml. blood and add to a graduated tube containing anticoagulant; either heparin or ammonium potassium oxalate is satisfactory.
2. Wash the red cells 3 times with 0.85% sodium chloride solution.
3. Centrifuge for 10 min. at 2500 r.p.m. after the final wash and draw off the saline.
4. Measure the packed volume of cells.
5. Add 1.6 vol. distilled water to the packed cells, suspend the cells, and mix thoroughly.
6. Add approximately one fifth the total volume of toluene and shake vigorously for 5 min.
7. Centrifuge at 2500-3000 r.p.m. for 30 min.
8. Remove the toluene layer and any denatured protein which may appear at the water-toluene interface with a capillary pipet.
9. Filter the hemoglobin solution through a small retentive filter; if not clear, return the filtrate to the filter a second time.

This hemoglobin solution may be used in the procedure described in the following section.

Determination:

Reagents:

1. 0.0833N Potassium hydroxide solution.
2. Acid ammonium sulfate solution.
   (a) Make a saturated solution of ammonium sulfate by suspending 900 gm. ammonium sulfate in distilled water to a total volume of 1000 ml. and dissolve by heating.
   (b) Let the solution cool to room temperature and leave for at least 24 hr. for the excess ammonium sulfate to crystallize.
   (c) To prepare the reagent dilute 200 ml. this saturated solution with 200 ml. distilled water, add 1 ml. concentrated hydrochloric acid, and mix well.

Procedure:

1. Measure 3.2 ml. potassium hydroxide solution into a test tube.
2. Add 0.2 ml. hemoglobin solution, mix quickly, and let stand exactly 60 sec.
3. Add 6.8 ml. acid ammonium sulfate, mix well by inversion, and filter. If necessary, pour through the same filter again. This filtrate will contain any fetal hemoglobin which may be present.
4. Determine the OD solution at 540 mμ using distilled water as a reference.
5. Dilute 20 c.mm. original hemoglobin solution in 5 ml. distilled water.
6. Determine the OD this solution at 540 mμ.

Calculation:

$$\frac{\text{OD filtrate} \times 100}{\text{OD original Hb sol.} \times 5} = \%\ \text{Fetal Hb}$$

NOTE: Any spectrophotometer or any filter photometer having a filter that gives maximum transmission at about 540 mμ may be used. If the scale of the instrument is graduated in transmittance only, the % may be determined and converted to optical density using the following formula:

$$\text{OD} = 2 - \log \%\ \text{T}$$

Any cuvet having a diameter between 12 and 20 mm. may be used.

Recognition of fetal red blood cells in the maternal circulation

Normal adult blood may contain up to 2% fetal hemoglobin. Higher values have been reported in mothers of infants suffering from erythroblastosis fetalis or from nonhemolytic anemia due to bleeding into the maternal circulation. The recognition of fetal cells in the maternal circulation may be of some importance in the prevention of erythroblastosis. Since rapid destruction of fetal cells in the maternal circulation in A-B-O incompatibility apparently protects the mother from Rh sensitization, it is thought, that in the absence of A-B-O incompatibility, therapeutic destruction of fetal cells in the maternal circulation may prevent erythroblastosis fetalis. Such therapy will depend on the early recognition (post-delivery) of fetal cells in the mother's blood.

In 1957 Kleihauer[532] described a modification of the Wright-Giemsa stain employing McIlvaine phosphate buffer with a pH of 3.4 (14.3 ml. citric acid and 5.7 ml. disodium phosphate) which allows differentiation of normal hemoglobin-A containing erythrocytes from erythrocytes containing hemoglobin-F. His method was originally used as a rapid screening test for thalassemia and other congenital anemias and is based on the fact that normal erythrocytes are not acid resistant, whereas fetal cells are acid resistant.[533]

Procedure:

1. Air dry films of peripheral blood.
2. Fix in 80% ethyl alcohol.
3. Wash.
4. Immerse in McIlvaine buffer for 10-15 min.
5. Wash.
6. Stain with Wright-Giemsa.
7. Dry and examine with high dry objective.

Interpretation: Normal (hemoglobin-A) erythrocytes are represented by shadows only. Fetal (hemoglobin-F) erythrocytes are acid resistant and remain intact.

Apt test

This test is used to distinguish ingested maternal blood from fetal blood in cases of gastrointestinal hemorrhage of the newborn and is based on the alkali resistance of fetal hemoglobin.

Method:

1. Suspend a small amount of bloody meconium in 10 ml. distilled water and add 0.2 ml. 10% NaOH.

If the solution turns opaque brown, the blood is from the mother, and if it remains pink, the blood is of fetal origin.

Electrophoresis[536]

1. Use horizontal bridge and veronal buffer solution of pH 8.6, ionic strength 0.06.
2. Use horizontal bridge and power supply with 500-volt outlet and Whatman electrophoresis paper cut into strips according to the width and length of the horizontal bridge.
3. Fill the chambers at both ends of the bridge with buffer and wet the filter paper with buffer by immersing it completely.
4. Blot the electrophoresis paper between 2 pieces of filter paper and place the blotted electrophoresis paper over the horizontal bridge. Make sure that the ends of the paper are inserted into the buffer-containing chambers at either end of the apparatus.
5. Make a vertical pencil line at about the center of the paper.
6. Apply small drops of hemoglobin solution approximately 0.003-0.005 ml. at small marks on the pencil line.
7. Connect the electrodes to the power supply, adjust to 350 volts and 12-15 ma.
8. Allow the electrophoresis to continue for 10-12 hr. At the end of the run, dry strips immediately in oven.

The original method employs 2 siliconized glass plates, one of which supports the electrophoresis paper while the other one covers it. It is held in place by clamps which distribute the pressure evenly.

Other methods of investigation of abnormal hemoglobins

These methods include tests for sickling (described in the discussion of sickle cell anemia), crystal violet stains to emphasize target cells, which occur in hemoglobin-C disease, and examination of unstained blood for intraerythrocytic inclusions, which occur in hemoglobin-C and hemoglobin-H disease.

Sickle cell anemia

Sickle cell anemia was first seen by Herrick[537] who observed peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia. He did not recognize this as a distinct clinical entity, but it is now recognized as such. The disease is a familial one occurring mainly in Negroes or mulattoes. It was generally believed that it was an intrinsic characteristic of the Negro until Cooley and Lee[538] reported a case in a 4-year-old American-born Greek boy. Since then, other cases have been reported in Italians, in Sicilians, and even in a boy of Scottish-Irish parentage. It has been found as a latent phenomenon in 6 or 7% of several series of supposedly normal Negroes. L. W. Diggs of the University of Tennessee has made a special study of this type of anemia. He states that the average age of death of these patients is 11 years.

In West Africa, the ancestral home of most Negroes, sicklemia received the attention of Russell and Taylor in 1932, Smith in 1934, Reid in 1936, and Evans in 1944 and 1945. Findlay, Robertson, and Zacharias[539] reported on the incidence of sickle cell anemia in the British West African colonies. In all, 5500 Africans were examined, of whom 12.4% showed the sickling trait. One half of the number were natives of the Gold Coast and French Togoland; the remainder came from Gambia, Sierra Leone, and Nigeria. Sickling was found in all tribes and no significant specific tribal differences were noted; 11.2% were males and 12.6% were females.

The protective mechanism of balanced polymorphism described in the discussion of hemoglobin-F applies also to hemoglobin-S. The protection may be due not only to the presence of hemoglobin-S but also to an increased level of gamma globulin found in the protected children.[540]

Clinical features of sickle cell disease (homozygous sickle cell anemia)

Sickle cell disease occurs in about 2 per 1000 American Negroes. There is high infant and child mortality with an early (several months of age) appearance of anemia. Enlargement of the liver and spleen, followed after many years by contraction of the spleen, is encountered. Frequent complications are leg ulcers, osteomyelitis, and heart disease. In addition to the 2 types of crises (hemolytic and aplastic)[541] occurring in all hemolytic anemias but rarely in sickle cell disease, there occur thrombotic crises in hemoglobin-S disease. These are due to vascular occlusions produced by the interlocked sickle-shaped cells.[542]

Sickle cell trait

Sickle cell trait is found in about 10% of American Negroes and is asymptomatic in most patients. Some patients show hematuria (renal congestion?) and may develop splenic infarcts or pulmonary infarcts during poorly pressurized high altitude flight and during anesthesia.

Blood picture

The blood picture in sickle cell anemia shows sickle-shaped erythrocytes, often not typical in stained spreads, but 75-100% are distorted in moist preparations. There is present a normocytic normochromic anemia with normal MCV and normal MCHC. Signs of regeneration in the blood are seen in an increase in reticulocytes, diffuse basophilia, the presence of nuclear particles, and nucleated red cells. There are anisocytosis, anisochromia, and poikilocytosis.

The differential blood count is variable, usually with a left shift of the leukocytes. There is also an increase in blood platelets. Bleeding and coagulation times are normal. There is a decrease in fragility, but normal sedimentation.

No hematologic changes are noted in sickle cell trait.

Demonstration of sickling of erythrocytes

Method I—in vivo anoxia of Scriver-Waugh[543]**:**

1. Place a rubber band around the finger for 5 min.
2. Obtain a drop of blood from the finger and quickly place it under a cover slip.
3. Seal the edges of the cover slip with petrolatum.
4. Observe for sickling for several hours.

Method II—metabisulphite method of Daland-Castle[544]**:**

1. Add 1 drop blood to 2 drops freshly prepared 2% aqueous solution sodium metabisulphite on a glass slide.
2. Cover with a cover slip and observe in 15-30 min.

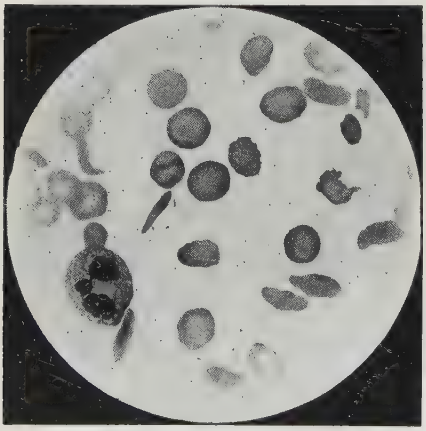

Fig. 429. Sickle cell anemia, stained film. (×950.)

With this method, sickling occurs promptly. In sickle cell **disease** 60-80% of the red cells may show sickling, whereas in sickle cell **trait** only a small percentage (5%) may show sickling.

To obtain permanent films, English[545] suggested that sickling be allowed to occur between 2 slides and these 2 slides then be separated in formaldehyde fumes released from heated formaldehyde tablets.

Electrophoresis of hemoglobin-S

In **sickle cell disease** the hemoglobin appears to be almost pure hemoglobin-S. A small amount of hemoglobin-F may be present. In infants, hemoglobin-F is seen naturally, but if it appears in older persons, the possibility of sickle cell–thalassemia disease must be considered. Hemoglobin-A is not present except when the pattern is obtained on a recently transfused patient.

In **sickle cell trait,** hemoglobin-S and hemoglobin-A can be identified. In sickle cell trait the hemoglobin-S component may amount to 45%, the remainder being hemoglobin-A. In comparison, in sickle cell disease, hemoglobin-S is usually over 50% and may reach 80-90%. Homozygous hemoglobin-S disease is represented by the following gene pattern; alpha-2^Abeta-2^S. The heterozygous form is represented by alpha-2^Abeta-2^A (hemoglobin-A) plus alpha-2^Abeta-2^S (hemoglobin-S). As stated previously hemoglobin-S is thought to be an allele of hemoglobin-A on the same locus.

Ferrohemoglobin solubility[545a]**:** The low solubility of reduced hemoglobin-S (ferrohemoglobin-S) may be used to differentiate hemoglobin-S from hemoglobin-D, which has identical electrophoretic mobility at pH 8.6.

Bone marrow findings

Bone marrow studies in sickle cell anemia have not been touched upon with much frequency. Sydenstricker[546] found the bone marrow to be abundant, bright red, and thin. Huck[547] and Sharp and Schleicher[548] confirmed these observations.

The bone marrow shows mainly erythroid hyperplasia involving all precursor forms of red blood cells. The marrow hyperplasia eventually produces bone changes which are similar to those seen in thalassemia, but in contrast to thalassemia radiologic evidence does not appear till adolescence or even later. The bone marrow may contain infarcted areas. In thalassemia infarcts are not usually seen. Rarely, megaloblastic erythropoiesis occurs in hemoglobin-S disease.

Nonhematologic findings

Urine: The presence of amino-aciduria has been reported. The common finding is a low specific gravity, as the kidneys in hemoglobin-S disease have lost some of their concentrating ability. An interesting common finding is the presence of hematuria in often unsuspected cases of sickle cell trait.

Plasma: There is a slight increase in gamma globulins and in the indirect van den Bergh test.

Pathology

Sickled red blood cells and congested capillaries are characteristic. There are a thrombocytic tendency, infarcts, fibrosis, and anemia. There is hemolytic jaundice with pigmentation. The marrow is hyperplastic[549] with evidence of accelerated hematopoiesis of all elements within the bone marrow. Unusual forms of red cells are found in specimens of bone marrow which have been prepared in formalin. The lymph glands show marked hyperplasia. A number of observers have noted phagocytosis of red cells by reticuloendothelial cells in the liver, spleen, and lymph glands. There are congestive splenic enlargement and early hemorrhage. There are siderotic nodules in the spleen. Fibrotic atrophy occurs late, as has been described by Diggs. There are hepatomegaly and some evidences of kidney degeneration. Leg ulcers are commonly seen.

The pathologic physiology of sickling was undetermined until Pauling demonstrated that the hemoglobin of sickle cell anemia (hemoglobin-S) had an electrophoretic mobility different from that of normal hemoglobin. He postulated this condition as a "molecular disease of hemoglobin."

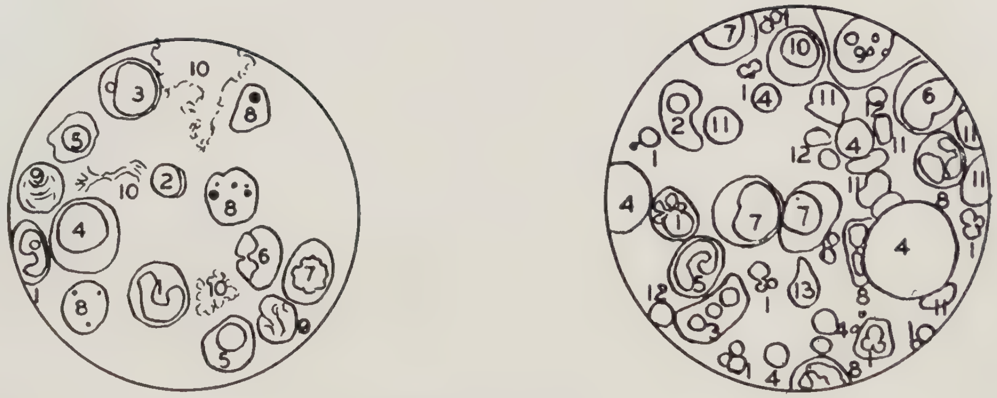
As previously stated, the globin fraction of hemoglobin-S contains valine in the beta chain in the location at which hemoglobin-A contains glutamic acid. This substitution produces profound changes so that the reduced hemoglobin-S is about 98 times more insoluble than oxygenated hemoglobin-S, whereas in comparison, reduced hemoglobin-A is only twice as insoluble as oxygenated hemoglobin-A. The low solubility and the viscous nature of reduced hemoglobin-S are responsible for the sickling phenomenon which consists of the formation of a semisolid hemoglobin gel in elongated sickle shapes called **tactoids.** This change begins at a hemoglobin-S concentration within the red cells of 10%. The tactoids form within the cell and in doing so stretch and distort the cell membrane. This process requires 3 conditions: (1) reduced oxygen, partial pressure below 45 mm., (2) a certain amount of time, 2-5 min., and (3) lowering of the pH.

Reduced oxygen tension is produced by high altitudes, flying, heart and lung disease, and anesthesia. The time factor necessary for the production of sickling is provided by the lengthened circulation time as seen in congestion and circulatory stasis. During stasis the lowering of the pH is accomplished by the accumulation of carbon dioxide. Shen and others[550] believed that a fourth factor was necessary, intravascular trauma. In the process of sickling the cells lose potassium and exchange it for sodium. The sickle cells are destroyed in the spleen.

The sickle cell trait is inherited as a mendelian dominant.

Eadie and Brown[551] have critically reviewed the literature on red cell survival studies. In sickle cell anemia it is known that when blood from a patient with the disease is transfused into a normal recipient cells disappear rapidly at first and then more slowly, with some cells living out a normal life span. The shortened survival time has been generally considered a function of the amount of abnormal hemoglobin in individual cells, those having the highest percentage of hemoglobin-S having the shortest survival time. These observers take exception to this view and suggest that random mechanical destruction plus normal senescence account for the disappearance rate in sickle cell disease. The cells in sickle cell trait have normal survival time.

As the new forms of molecular diseases of hemoglobin are uncovered, the problem of hemoglobin-S disease becomes more complex. Combinations of sickle cell with hemoglobin-C have been described, and other combinations will undoubtedly be forthcoming. This second type has a lower frequency than sickle cell disease, and Neel indicates that in 6% of Negro families in which sickle cell disease was present, the disease was due to a combination of sickle cell and hemoglobin-C. There is one gene for hemoglobin-S and one gene for hemoglobin-C. The disease is similar to hemoglobin-S disease but much milder. In the peripheral blood film target cells are prominent.



Sickle cell anemia

Blood film, regeneration

Wet preparation

Bone marrow

Fig. 430

The electrophoretic pattern may show hemoglobin-F in addition to hemoglobin-S and hemoglobin-C. The third type is a combination of sickle cell with thalassemia, which accounts for many of the cases of sickle cell disease in Caucasians.

Silvestroni and Bianco[552] call attention to the combination in which one parent has sickle trait and the other thalassemia trait; the offspring may have a hemolytic disease which they term microdrepanocytosis. On the basis of genetic studies in 11 families, these authors are of the opinion that the genes for sicklemia and microcythemia (thalassemia) are inherited independently of one another and are located on different chromosomes. This disease is similar to hemoglobin-S disease with moderate to severe manifestations. The hypochromia of the peripheral blood film in association with target cells and occasional sickle forms is suggestive of thalassemia-sickle cell disease. The electrophoretic pattern reveals hemoglobin-S, hemoglobin-A, and hemoglobin-F.

Some of the other combinations that have been described are sickle cell hemoglobin/hemoglobin-D disease and sickle cell hemoglobin/hemoglobin-E disease.

Hemoglobin-C disease

Hemoglobin-C is an allele of hemoglobin-A and hemoglobin-S. Hemoglobin-C is inherited as a mendelian dominant. In the **trait** no anemia is present, but target cells may be seen in the film of the peripheral blood. In the disease (homozygous form) numerous target cells are seen as well as intraerythrocytic crystals, especially after splenectomy.[553]

Ovalocytosis (elliptocytosis)

Ovalocytosis is a familial phenomenon characterized by large numbers of oval or elliptical red cells which appears as a nonsex-linked mendelian characteristic in certain individuals. The etiology is unknown. To date 75 authentic cases and 25 questionable cases have appeared in the literature. Dresbach[554] described a patient in whom every red cell was of oval shape; the blood was otherwise normal. Bishop[555] described a patient in whom 75% of the erythrocytes were oval, with the blood otherwise normal. Sydenstricker[556] reported a case of a Negro in whom 90% of the red cells were oval. Lawrence[557] reported a case of a female caucasoid, 32 yr. of age, with many oval red blood cells. Bernhardt[558] described a female caucasoid, 34 yr. of age, with oval red cells. Bernhardt termed this condition ovalocytosis. Miller and Lucas[559] have reported 9 additional cases in 4 generations. The diagnosis of elliptocytosis should not be made unless over 25% of the cells show well-developed elliptical shapes.

It must be understood that elliptical erythrocytes are not poikilocytes of any of the known anemias, including sickle cell anemia. This is a congenital anomaly compatible with an otherwise normal individual. It must be recalled that all mammals except the terrestrial family Camelidae show circular erythrocytes. Conversely, among the lower vertebrates, the red blood cells are elliptical with the single exception of the marine family Cyclostomata. Dresbach in 1902 first reported elliptical red blood cells in human beings. In the subsequent cases reported, it was found that males and females are equally affected. Ovalocytosis has been observed in a number of different nationalities. Its familial tendency was proved by Hunter and Adams[560] in 1929.

As just stated the etiology is unknown. It has been laid at the door of faulty erythropoiesis, influences of the blood plasma, the inherent quality of the cells, racial characteristics, and anoxemia, and it has been suggested that the etiology is similar to that of sickle cell anemia. Normal erythrocytes are unaltered by the plasma of persons with this anomaly. By means of autopsy, bone marrow and splenic punctures, it has been shown that these cells are not elliptical when they are formed in the bone marrow but assume that shape when subjected to the influence of some unknown constituent of the plasma or extramarrow tissues. That normal erythrocytes are unaffected by the plasma from a case of ovalocytosis suggests a second intraerythrocytic susceptibility to the extraerythrocytic influence, either or both of which may be congenital.

Miller and Lucas comment upon the fact that mechanical effects, temperature, normal blood serum, isotonic and hypotonic saline washing, picric acid, carbon dioxide, oxygen, cholesterol, etc., all failed to affect the constancy of the ellipsoid state of the red cells. Terry has shown that elliptical erythrocytes are more resistant to hemolytic agents and have a decreased fragility. He[561] has shown that these cells are heavier than round cells. Pollock and Dameshek[562] observed that potassium cyanide increased the number of elliptical erythrocytes very rapidly. Neither the marrow erythroblasts nor the reticulocytes show the oval contours.

The medicolegal point about this phenomenon is interesting; namely, within certain limits it may be used as a means of identification of both persons and paternity.

Motulsky et al.[563] divide hereditary elliptocytosis into 4 classifications, as follows:

Group I—normal round erythrocytes
Group II—oval erythrocytes
Group III—elliptical erythrocytes
Group IV—rod-shaped or cigar-shaped erythrocytes

These authors state that the predominance of Group IV cells favors a diagnosis of hereditary ovalocytosis, whereas an association of elliptical cells and other deformed cells is more indicative of symptomatic ovalocytosis such as occurs in pernicious anemia, Cooley's anemia, severe iron deficiency, leukemia, cancer, and severe anemia associated with infection. In 1 of 3 cases presented, the survival time of transfused red cells was found reduced to 45 days. This case presented other evidence of hemolysis. On the other hand, patients with normal survival times showed no hemolytic features. Motulsky et al. call attention to the similarity of hereditary ovalocytosis to other diseases characterized by deformity of the red cell and shortened life span of these cells, such as occur in sickle cell anemia, hereditary spherocytosis, and thalassemia major. Just as in these syndromes, in which there are a "disease" group and a nonsymptomatic "trait" group, ovalocytosis may likewise be subdivided. Red cell survival times in the trait group are normal, whereas in the disease group they are shortened. This survival time difference in the 2 groups is not dependent on elliptocytes; the cause for such differences remains unknown.

Molecular disease of hemoglobin accounts for the changes in sickle cell anemia, thalassemia, and other diseases, but electrophoretic studies in 2 of these 3 cases were normal and fetal hemoglobin was not increased. Motulsky et al. review the literature on symptoms and hereditary patterns in the hemolytic syndromes associated with erythrocyte shape anomaly and show the many points of resemblance between elliptocytosis and the other hemolytic groups. The hereditary pattern is considered a mendelian dominant. Splenectomy is advised in the severe condition but not in the nonhemolytic or compensated form of the disease.

HEMOLYTIC ANEMIAS DUE TO EXTRACORPUSCULAR DEFECTS

Introduction to immunohematology

Immunohematology, a term proposed by Chauffard and Troisier[564] in 1908, in recent years has attracted the attention of clinicians and investigators. The discovery of the mechanisms involved in Rh sensitization perhaps gave this field its greatest stimulus, and today the literature is replete with references to immunologic mechanisms as operative in many blood dyscrasias. Although antigen-antibody relationships have been well established for isoimmune phenomena related to red cells, knowledge of the phenomena of autoimmunity is of relatively recent origin.[565] Evans and his co-workers[566] suggested a common etiology of immunologic character for thrombocytopenia and acquired hemolytic anemia; Harrington and his group[567] brilliantly completed the picture as related to thrombocytopenia; Moeschlin and Wagner[568] have added the leukocyte to the immunologic fold. The rapidly expanding literature in the field of immunohematology contains numerous studies on clinical states in which one of the formed blood elements is predominantly involved or combinations of two or more of the elements are affected.

Immunohematology embraces all disease complexes that arise from the action of autoantibodies on the hematopoietic system of the individual and 3 major groups of diseases: (1) autoimmune hemolytic anemia due to antierythroid antibodies, (2) autoimmune thrombocytopenia due to antiplatelet antibodies, and (3) autoimmune leukopenia due to antileukocytic antibodies (and combinations of these).

Autoantibodies

Chemically, autoantibodies are globulins mainly gamma and beta but also alpha. They form in response to an antigen which is principally protein in nature but may also be a low molecular polysaccharide, either free or attached to protein. If these antibodies react best at low temperature (4° C.) and not at body temperature (37° C.), they are called cold autoantibodies. If cold antibodies are strong, their activity may well extend into the 37° C. zone. If the antibodies act best at body temperature, they are called warm autoantibodies. Each one of these antibodies may be bivalent (complete), acting best in saline medium, or univalent (incomplete), acting best in high molecular protein medium.

They are demonstrable with the Coombs technic. The hemolyzing antibodies require the presence of complement or properdin or both.

Formation of autoantibodies

Various theories have been advanced as to the circumstances which lead to the formation of antibodies against the individual's own cells.

Hapten theory: The cells are immunologically altered by the action of bacteria, viruses, enzymes, chemicals, and drugs so that they act as antigens.

Dysproteinemia theory: Osgood has postulated that autoimmune antibodies are due to a dysproteinemia in the course of which abnormal proteins are produced which happen to coat normal blood elements so that they will act as antigens. The occurrence of this type of mechanism in cirrhosis is generally accepted.

Graft versus host reaction[569]**:** The autoantibodies are abnormal antibodies produced by abnormal cells which themselves are accepted and tolerated by the body. This idea is based on experimental work of Simonsen, who produced hemolytic anemia in embryonic chicks after intravenous implantation of splenic cells of unrelated donors. In relation to symptomatic hemolytic anemia, Burnet's work is even more important, as he showed that lymphoma cells, produced by somatic mutation, survive in the host but retain their ability to produce antibodies which at times are against the patient's own red blood cells.

Isolated antigen: The theory of the isolated antigen does not apply to immunohematology since it states that substances not in direct contact with the reticuloendothelial system, such as lens tissue, thyroxin, spermatozoa, etc., may give rise to antibodies when released into the circulation.

Nature of autoantibodies[570]

Autoantibodies: Autoantibodies may be complete or incomplete agglutinins or hemolysins, acting against the individual's own cells.

Isoantibodies: Isoantibodies may be either complete or incomplete agglutinins or hemolysins. They are antibodies formed to species-specific antigens (usually blood factors) which are foreign to the individual. They may be cold or warm antibodies. They are included in this chapter because at times they lose their specificity and become "public" antibodies, directed against a large group of cells, including blood elements.

Heterogenic antibodies: These are antibodies which react with antigens different from the antigen which stimulated their production. Examples of such antibodies are those appearing in infectious mononucleosis and syphilis. Those in the first case react with sheep cells and in the second case with beef heart extract, though neither sheep cells nor beef heart muscle has an etiologic relationship to the diseases mentioned. Cold antibodies probably fall into the group of immune heterogenic antibodies, being the result of cross-reaction between, for instance, the mucopolysaccharide component of an infecting microorganism and a chemically similar substance in one of the blood cells. It must also be mentioned that there is an increasing number of reports of cold antibodies with blood group specificity.

Acquired hemolytic anemia of the autoantibody type

Clinical classification

Idiopathic hemolytic anemia: As far as known, there is no underlying disease present which could account for the occurrence of this anemia. This type of anemia occurs at any age and shows some preference for women. The cause of the disease may lie in a pathologic constitutional ability of the patient to produce a large number of various antibodies following relatively minor stimulation. An acute form of this type of anemia, which is of short duration, has in the past been referred to as **Lederer's anemia.** The clinical picture is that of all hemolytic anemias except that there is an associated tendency to thrombus formation, possibly due to release of phospholipids from destroyed erythrocytes. These thrombotic episodes are often heralded by sludging of capillary blood, visible in conjunctival and subungual capillaries. The spleen is usually enlarged.

Symptomatic hemolytic anemia: In this group fall the hemolytic anemias accompanying tumors and diseases which frequently lead to production of antierythrocytic antibodies. These conditions are chronic lymphatic leukemia, lymphomata, aplastic anemia, infectious mononucleosis, macroglobulinemia, ovarian tumors, lupus erythematosus and other collagen diseases, viral diseases such as hepatitis and viral pneumonia, and cirrhosis. It is interesting to note that multiple myeloma (high gamma globulin) is seldom associated with hemolytic anemia. In this group also fall the hemolytic anemias which follow the administration of drugs. These anemias are not synonymous with the hemolytic enzyme-deficient anemias previously discussed, which are precipitated by the administration of certain drugs.

Laboratory findings

Hematological findings

Red blood cells: The anemia is frequently macrocytic in type but differs from pernicious anemia by the presence of moderate reticulocytosis. Occasional spherocytes, siderocytes, normoblasts, and polychromatic cells are seen. The osmotic and mechanical fragility may be slightly increased, depending on the number of spherocytes. Aplastic and hemolytic crises may also occur. Autohemolysis is usually excessive. Blood samples frequently show spontaneous autoagglutination. The sedimentation rate is increased, often showing an ill-defined zone between the plasma and red cell mass produced by reticulocytes.

White blood cells: Although acute hemolysis may lead to leukocytosis, the white cell count in chronic hemolytic anemia may be depressed to leukopenic levels. Occasional erythrophagocytotic monocytes can be seen.

Platelets: Platelets are normal or depressed.

Nonhematologic findings

The findings in urine and serum are those of any hemolytic anemia (see introduction to hemolytic anemias).

Serologic findings: The antibodies involved in acquired hemolytic anemia are autoantibodies which act on the patient's own red blood cells but which frequently spread their activity to include all normal human red blood cells (isoantibody-like).

Two types of antibodies are distinguished on the basis of their in vitro characteristics: (1) warm antibodies, which act in vitro at 37° C. but are also active at lower temperatures, and (2) cold antibodies, which act best at 4° C. in vitro but extend their activity up to 28°-32° C. (room temperature) and are seldom active at 37° C.

Warm antibodies are usually of the incomplete variety and occur more frequently in hemolytic anemia than do cold antibodies. They are adsorbed by the red cells and therefore may or may not be present in the plasma, but they can be eluted from the red cells. Wiener, who calls these antibodies hyperimmune, and others showed several years ago that these antibodies may have blood group specificity and are usually linked to the Rh system (anti-**rh″**). Like most antibodies, they are gamma globulins (gamma-1 and gamma-2) and are of small molecular weight (sedimentation constant 7-S). Coated red cells are agglutinated by Coombs serum (antigamma globulin serum), and the reaction can be prevented by neutralizing the Coombs serum with small amounts of gamma globulin. On the other hand, there are sensitized red cells which are agglutinated by such neutralized Coombs serum (antinongamma globulin serum). By immune electrophoretic methods it has been shown that certain antibodies contain not only gamma globulin but also beta-2 and alpha-2 fractions. It may be that these antibodies are specific for some intermediate substance such as one of the complement components which under the influence of the antibody are bound to the red cell which then secondarily becomes coated with a gamma globulin type of antibodies.

Cold antibodies are usually complete antibodies and are frequently nonspecific in nature. Wiener,[571] who calls these antibodies simple, showed that some cold antibodies have blood group specificity. The particular antigen involved is named antigen **I**[572] and the antibody anti-**I**. The immune antibody—and this applies generally—is at first specific for a single antigen but later also affects related antigens.

The term nonspecific implies that the etiologic antigen has not been identified, but it may also connote that it acts on an antigen common to all red blood cells. Thus while cold antigens may be specific, they frequently act on all red blood cells and sometimes even on heterogeneous red cells. Electrophoretically, the cold antibodies are gamma-1 (beta) globulins with a sedimentation constant 16-19-S (macroglobulins). They act best at 0°-4° C., but they may have a wide thermal range and extend up to 28°-32° C. If they are hemolytic, they interact with complement best at an acid pH of 6.3. A special type of cold hemolysin is Donath-Landsteiner cold hemolysin which unites with the red blood cells best at a temperature of 0°-4° C., but hemolysis does not occur until the temperature rises to over 15°-40° C. The latter hemolysin is called bithermic in contrast to the nonthermic hemolysin which acts best at a pH of 6.3. In the latter case both reactions, binding of the complement and lysis of the red cells, occur at the same temperature.

Laboratory investigation of warm antibodies

Direct antiglobulin test (direct Coombs test): This test represents a gamma globulin-antiglobulin reaction, as human erythrocytes sensitized by gamma globulin antibodies are agglutinated by an antihuman globulin serum prepared in rabbits. This test should be performed at 4° C., at room temperature, and at 37° C., always with appropriate controls. For the detection of warm antibodies only, performance of the test at room temperature and at 37° C. suffices. The sensitivity of this test can be improved by using enzyme-treated cells (trypsin, papain, albumase, etc.). A positive test (agglutination) proves the presence of an antibody on the surface of the patient's erythrocytes (for details of technic see discussion of blood groups).

Agglutination of cells suspended in albumin: Patient's washed cells are transferred to 20% albumin to produce a 5% suspension. After 1-2 hr. incubation at 37° C. sensitized cells will undergo autoagglutination.

Agglutination of trypsinized cells: Patient's cells are washed, enzyme treated, and after incubation in albumin (see above) will frequently show agglutination.

Preparation of trypsin stock solution:

1. Prepare a 1% stock solution trypsin powder in phosphate buffer, pH 7.4.
2. Filter through Whatman No. 1 filter paper and distribute into small cubes and store frozen in the freezer.
3. Add 1 part stock trypsin solution to 10 parts 2% saline suspension.
4. Incubate in water bath at 37° C. for 10 min.
5. Wash the cells 3 times with saline.
6. Drain saline and add fresh saline to make a 2% cell suspension.
7. Suspend 2 drops trypsinized cells in 2 drops albumin.
8. Incubate at 37° C. for not longer than 1 hr. and examine for agglutination. Do not centrifuge.

It must be pointed out that there are antibodies which can be detected by the indirect Coombs technic but which fail to react with trypsinized cells (**K**, **Fy**^{a}, etc.).

Nongamma globulin antiglobulin test (gamma globulin neutralization test or complement antiglobulin test): There are some autoantibodies that do not react with antigamma globulin Coombs serum, such as anti-**H**, anti-**Jk**^{a}, and anti-**Fy**^{a}. These antisera are apparently specific for human complement (C^{1}) rather than for gamma globulin. The direct Coombs test can be inhibited by the addition of human gamma globulin. On the other hand, the addition of human gamma globulin fails to inhibit a positive nongamma globulin antiglobulin test in which complement is involved. This test is inhibited by the addition of human alpha and beta globulin. In the execution of the test, antiglobulin serum is partially neutralized with human gamma globulin, and the direct Coombs test is performed utilizing the partially neutralized serum.

Indirect antiglobulin (Coombs) test: The purpose of this test is to detect antibodies in the patient's serum by incubating Group O Rh-negative cells with the patient's serum. If the patient's serum contains incomplete antibodies, they will attach themselves to the red blood cells, thus sensitizing them. The direct Coombs test is then performed on these in vitro sensitized cells. The use of albumin or enzyme-treated cells will increase the sensitivity of this test but makes several control procedures necessary.

Specificity of antibodies: After it is established that warm antibodies are present in the serum, their specificity can be established by performing the albumin and the direct Coombs test with the serum on a panel of cells containing most of the known antigens.

Laboratory investigation of cold antibodies

The tests employed are essentially the same as for the warm antibodies but require certain modifications.

It should be mentioned that rouleaux formation can at times be mistaken for cold agglutination though microscopically it is usually easy to differentiate from true agglutination. Rouleaux formation can be disturbed by pressing on the cover glass, and it is usually diminished by adding saline or lecithin to the serum. Whereas cold agglutination usually disappears at 37° C., rouleaux formation may become even more pronounced.

Test for cold agglutinins:

1. Collect 4 ml. blood in 1 ml. 3.8% sodium citrate. The plasma dilution will be 1:4.
2. Set up 4 sets of 7 Kahn tubes, adding 0.5 ml. saline to each tube.
3. To the first tube of each set, add 0.5 ml. 1:4 diluted serum, mix, and then transfer 0.5 ml. to the next tube, etc. Each set of tubes should also contain 1 control tube.
4. To each tube then add 0.5 ml. 2% suspension of Group O cells washed in saline.
5. Allow these sets to remain at the following temperatures: 4°, 16°, 22°, and 37° C. for 12-20 hr. and then examine for agglutination.

Test for cold hemolysin: See explanation of acid hemolysis test in discussion of paroxysmal nocturnal hemoglobinuria.

Test for hemolysis:

1. Divide patient's blood and normal control blood into 2 test tubes each and allow to clot.
2. Place 1 tube of each set in an ice bath (3°-4° C.) for 20 min. and then transfer to a 37° C. water bath for 1 hr.
3. Examine for hemolysis.

The second tube of each set is left at room temperature.

Antiglobulin test: The antiglobulin test may be positive at room temperature in the face of a high-titered incomplete cold agglutinin associated with hypergammaglobulinemia due to liver disease, infection, collagen disease, etc. These incomplete antibodies may be distinguished from the complete cold agglutinins by using neutralized Coombs serum which does not inhibit the reaction of true cold agglutinins which interact with complement (see discussion of cold agglutinins and of gammaglobulin neutralization test). Further 7-S gamma globulin can be eluted from the red cells, and these eluates will react with other red blood cells, whereas nongamma globulin antibody eluates will not do so.

Chronic and acute hemolytic anemias due to the presence of cold agglutinins

Congenital and acquired syphilis[573] are rarely accompanied by chronic hemolytic anemias due to cold agglutinins. Viral pneumonia[574] frequently leads to an acute hemolytic anemia due to the presence of abnormally high titered cold agglutinins. A paroxysmal, nonsyphilitic form of hemolytic anemia due to cold agglutinins has also been described. In all these cases, peripheral vascular occlusion leading to gangrene is an important complication. The serum may contain cryoglobulins. Cryoglobulins are tested for by simply exposing the serum to 4° C. for a period of 12 hr. to see whether it gels at that temperature.

Hemolytic anemias due to isoantibodies (erythroblastosis fetalis and hemolytic transfusion reactions)

Erythroblastosis fetalis

This is often a fatal condition which has been the subject of considerable investigation. It was originally described as being due to an intragroup hemolytic reaction incident to the mating of an Rh-positive father with an Rh-negative mother. It has been well described clinically by Buhler et al.,[575] who reported on this disease in dizygotic twins. The clinical manifestations and their development will depend on whether the predominate pattern be evidenced by edema or icterus or simply by the blood findings of anemia and an increased number of nucleated red blood cells. Hydrops when associated with either of the other two is fatal, and the infant is either stillborn or dies immediately after birth. Jaundice is absent at birth but appears within a few hours to several days, depending on the severity of the disease process. Potter and Adair[576] point out that neither the anemia nor the increased nucleated red blood cells alone are sufficient for a diagnosis of erythroblastosis fetalis, and many cases so diagnosed with subsequent recovery are probably erroneous. Buhler et al. record the symptoms in infants as follows: lethargy and exhaustion occur; symptoms may develop rapidly, depending upon the rate of blood destruction; petechial hemorrhages may appear; the heart is often enlarged; the pulse is rapid and weak; usually fever is not present; the liver and spleen are enlarged; and due to deposition of bilirubin and heme in localized areas of the brain, a syndrome called **kernicterus** may develop which may quickly cause death. McKinley[577] records the early symptoms of kernicterus as convulsions, neck retraction, respiratory paralysis, and drowsiness.

Danis and Anderson[578] consider the syndromes of congenital hydrops, erythroblastosis fetalis, icterus gravis, and anemia of the newborn, one condition, i.e., a condition known as icterus gravis neonatorum.

Laboratory findings,[579-583] are those of a macrocytic hyperchromic, hypocythemic anemia associated with a hemolytic type of jaundice. There is an increase in the nucleated red cells. Hemoglobin varies from 25-60%. The red cell count is from 1,000,000-3,000,000. Reticulocytes are increased to from 15-20%. Poikilocytosis and anisocytosis are present. Leukocytosis is often marked, with an increase in the young white forms. The erythrocytes in erythroblastosis due to Rh incompatibility have been shown to have a decreased oxygen-carrying capacity and decreased glycolytic rate.[584]

Platelet counts are inconstant, and fragility tests are variable. Bleeding time is often prolonged; the coagulation time is not affected. The urine contains bilirubin. The stools may be acholic but more often are not.

Pathologic features are a universal hydrops, edematous tissues, ascites, hydrothorax, and hydropericardium if the infant dies of heart failure due to the anemia. If heart failure is absent, hemolytic jaundice is the outstanding finding.

Microscopically, the tissues show extramedullary hemopoiesis with islands of erythropoiesis occurring in the liver, spleen, adrenals, and kidneys and occasionally in other organs. The bone marrow is hyperplastic. Bile deposition is noted in the nuclear areas of the brain. The placental pathology is characteristic, i.e., increase in size, grayish or icteric color, and friable, edematous villi. Microscopically the villi are enlarged, and the vessels are filled with nucleated red cells.

Erythroblastosis fetalis is a hemolytic anemia of the fetus and newborn due to the action of antierythrocytic isoantibodies transferred across the placenta from the mother to the fetal circulation. The hemolytic anemia leads to jaundice because of the increase in indirect bilirubin (toxic!) and may also lead to heart failure (edema, hydrops). The sensitization of the mother can be produced by any antigen which she lacks and is in no way confined to the Rh system. Though erythroblastosis due to Rh incompatibility was the first form to be described, we now believe that A-B-O erythroblastosis is twice as common but is usually not clinically as severe and dangerous as Rh erythroblastosis. The other blood factors are of much less importance in the pathogenesis of erythroblastosis. If the sensitization of the mother is produced by pregnancy, usually the first pregnancy will not then be affected. Sensitization during pregnancy follows the release of fetal red blood cells into the maternal circulation, especially during delivery. Only a very small amount of fetal blood is needed to produce such sensitization. Operative obstetrical procedures such as cesarean section, abortion,

etc. tend to increase the incidence of sensitization. If the sensitization is produced by the administration of parenteral blood, the firstborn child may develop erythroblastosis fetalis.

Frequency of sensitization: Many factors determine the incidence of erythroblastosis fetalis (see discussion of blood groups).

1. Contact with a foreign antigen is not synonymous with sensitization. Not all women exposed to sensitization will actually develop antibodies, as apparently constitutional factors determine the ease with which they are produced.

2. Not all antigens are equally antigenic. In the Rh group in order of decreasing potency, the antigens are **Rh_0**, **rh′**, **hr′**, **rh″**, and **hr″**, and in the other blood groups they are **A**, **B**, **K**, **Jk^a**, **Fy^a**, **k**, **s**, and **Wr^a**. References are given to rare antigens causing erythroblastosis (**M**,[585] **U**[586]).

3. The A-B-O type of fetal red blood cells may affect the incidence of erythroblastosis. On one hand, the A-B-O type of the fetal cells may be responsible for the production of so-called A-B-O erythroblastosis. On the other hand, it influences the frequency of Rh sensitization and thus the frequency of Rh erythroblastosis. In cases of fetal-maternal Rh incompatibility, if the fetal cells are A-B-O compatible with the mother cells, they are not destroyed within the mother's circulation and may thus accumulate to reach sensitizing levels. If the fetal cells circulating within the mother's blood stream are A-B-O incompatible with the mother's blood, they are probably rapidly destroyed in the maternal circulation and are thus prevented from reaching sensitizing proportions.

4. As far as Rh erythroblastosis is concerned, it is important to know whether the Rh-positive husband of an Rh-negative woman is homozygous or heterozygous for the Rh factor involved. The more frequently and persistently an Rh-negative woman is exposed to sensitization, the more likely she is to eventually become sensitized. Thus a woman mated to a homozygous male is more likely to become sensitized than one mated to a heterozygous male.

5. The secretor state of the baby is important. Nonsecretor babies are not as well protected against the action of maternal isoantibodies as are secretor babies who are able to neutralize the antibodies before they reach the red blood cell. The secretor state is inherited but is independent of the blood groups and is most easily determined by testing the saliva for A and B blood group substances.

Erythroblastosis due to Rh incompatibility and its laboratory diagnosis

The prenatal investigation of any patient should include determination of the A-B-O blood group and of the Rh factor. If she is Rh negative, the presence of an anti-Rh antibody and its titer should be determined at about 6-7 mo. of gestation, again a few weeks before expected delivery, and finally a few weeks after delivery. This procedure should be followed with each pregnancy (including the first). The antibody titer is important in the discovery of erythroblastosis of the firstborn and is of importance if the titer is rising. (Always place the originally titrated serum in the freezer and retitrate it in conjunction with the second or third specimen). The actual level of the titer may bear little relationship to the severity of erythroblastosis, but it serves as a warning signal. We like to screen all multiparous women and all women who have a history of having received a transfusion for atypical antibodies (Hemantigen*), irrespective of their Rh factors. If atypical antibodies are found an attempt should be made to identify them (Panocell*).

The result of the action of the transmitted antibodies on the fetal red blood cells is their destruction and the liberation of indirect acting (nonconjugated) bilirubin which is insoluble in water and is transported in the blood stream linked to serum albumin. The poorly developed hepatic enzyme system of newborn and premature babies is unable to conjugate all the oncoming direct bilirubin to glucuronic acid. The nonconjugated bilirubin is not excreted by the liver or the kidneys and therefore accumulates in the tissues. It is associated with the "absolute heme pigment" of Abelson and Boggs, for the determination of which these authors describe an easily performed method.[587]

If an Rh incompatibility exists irrespective of the result of the titer determination, the newborn baby's red blood cells should be tested for the A-B-O and Rh types and for sensitization by the Coombs technic.[588] The baby's venous blood is at times preferable to cord blood, which may show a lower bilirubin titer and may also be contaminated with cord jelly. In rare cases a false negative

---

*Knickerbocker Laboratories, New York, N. Y.

Coombs test may be produced because of antibodies with blocking action, and it should also be remembered that the baby may actually be **Rh_0** negative and that the erythroblastosis may be due to some other factor than Rh. The mother's blood should be tested for atypical antibodies.

The level of the indirect reacting bilirubin in the baby's serum is measured at birth to obtain a base line and again within 6 hr. postpartum. In a newborn infant almost all the bilirubin measured is of the indirect variety. The following bilirubin levels are indications for exchange transfusions, according to Allen and Diamond[589]: birth level of 7 mg., a rise of 1 mg./hr., and a level of above 20 mg.

A-B-O erythroblastosis and its laboratory diagnosis

A-B-O erythroblastosis[590, 591] occurs mainly in type O women who apparently more readily develop high titer anti-**A** and anti-**B** antibodies than do type A and type B women. Wiener postulates that group O serum contains in addition to anti-**A** and anti-**B**, a third agglutinin called anti-**C**, directed against a factor **C** contained in agglutinogens A and B. Anti-**C** antibody is presumed to be able to cross the placental barrier more readily than anti-**A** and anti-**B**. On the other hand, one can assume that anti-**A** and anti-**B** antibodies are not homogeneous but are made up of multiple fractions. Thus Fischer on the basis of differential agglutination with anti-**A_1** shows that in newborn group A infants the percentage of agglutinable cells varies widely from one individual to another. He believes that this is due to the fact that the Group A infant may contain group A_1 and group A_2 cells and that the mother's antibodies act only against the A_1 erythrocytes.

Fascinating, though not proved, is the question of immunologic tolerance and its relationship to the incidence of erythroblastosis. Animals exposed to antigens in fetal life may fail to develop antibodies against this particular antigen in later life. One can thus assume that a group O fetus of a group A woman is exposed to A substance in utero and may therefore in later life not so readily form anti-**A** antibodies.

The jaundice is usually light, and the direct Coombs test on fetal red blood cells is usually negative. In the mother's serum the titer of the naturally occurring isoantibodies is elevated and is often exceeded by the titer of an immune antibody. It may be detectable after neutralization of the isoantibodies by Witebsky substances (blood group substances A and B).

The hemolytic anemia is usually moderate and characteristically the peripheral blood film shows the presence of spherocytes. On occasion, normoblasts are seen.

Tests for A-B-O erythroblastosis

Witebsky slide test:

1. Divide a slide into 3 compartments and place it on a heating viewing box.
2. Into the first compartment, place 1 drop mixture 1 part normal adult serum to 2 parts bovine albumin.
3. Into the middle compartment, place 1 drop normal adult AB serum and into the third compartment place 1 drop normal saline.
4. Add 1 drop heavy suspension cord blood to each solution.
5. Mix and examine for agglutination not longer than 2 min.

Cord red blood cells of infants with A-B-O erythroblastosis are agglutinated most strongly in the normal AB serum and less strongly in the albumin-serum mixture. The reverse is frequently true of Rh erythroblastosis.

Control: Set up a similar series of solutions and add 1 drop heavy suspension normal blood.

Witebsky neutralization test for anti-A and anti-B immune antibodies:

1. Prepare unneutralized serum by separating serum from clotted whole blood.
2. Prepare neutralized serum. To 1 ml. serum add 0.1 ml. concentrated A and B substances; allow to stand for at least 1 hr.
3. Prepare 2% cell suspension in saline of A and B cells which have been washed once. Also prepare 2% suspension of A and B cells in 20% albumin.
4. Titer of isohemagglutinins:
    - (a) Prepare 2 sets serial dilutions of unneutralized serum in normal saline diluting from undilute to 1:1024. Each tube should contain 0.1 ml. serum dilution.
    - (b) To 1 set of tubes add 0.1 ml. 2% saline suspension of A cells and to the second set of tubes add 0.1 ml. 2% suspension of B cells.
    - (c) Do not incubate. Centrifuge at 1000 r.p.m. for 1 min. and read the isohemagglutinin titer.

Examination of neutralized serum:

1. Using neutralized serum prepare 2 sets of serial dilutions in saline from undiluted to 1:16. Each tube should contain 0.1 ml. of serum dilution.
2. To 1 set add 0.1 ml. 2% A cells suspension and to the second tube 0.1 ml. B cells suspension.
3. Mix, centrifuge, and read.

If the isohemagglutinins have been neutralized, no agglutination will occur, or it will be only weakly positive in the first tube.

Titer of immune antibodies:

1. Using neutralized serum, prepare 2 sets of

serial dilutions of serum in 20% albumin. Each tube should contain 0.1 ml. serum-albumin mixture. The dilution should be from undiluted to 1:128.

2. To the first set add 0.1 ml. 2% suspension of A cells in 20% albumin and to the second set add 0.1 ml. 2% suspension of B cells in albumin.
3. Incubate for 30 min. at 37° C.
4. Shake, centrifuge at 1000 r.p.m. for 2 min., and read.

If an immune antibody is involved, it will show a high titer in the high protein test.

Ion exchange column chromatography: Kochwa[590] points out that the distinction between so-called natural agglutinins, which do not cross the placenta and so-called immune agglutinins which do cross the placenta cannot be maintained, as all agglutinins are basically immune in type. (Natural antibodies are immune in origin due to contact with plants, seeds, and foods containing A and B substances.)

Kochwa was able to separate the isoagglutinins which crossed the placenta from the remaining serum proteins by ion exchange column chromatography.

Treatment of erythroblastosis fetalis[585, 586, 591]

A single laboratory finding on the infant's blood, such as a high or low hemoglobin, a high or low bilirubin level, erythroblastemia, or reticulocytosis, has no diagnostic value. A positive Coombs test is diagnostic; a negative one does not rule out erythroblastosis. A premature infant may have a low cord bilirubin titer and a sharp rise later on. It may be that Boggs absolute heme pigment determination will prove to be a better criterion of the severity of erythroblastosis than bilirubin levels.

The treatment of choice at the present time is exchange transfusion and therefore involves the laboratory. The blood used for the exchange must be compatible with the mother's blood and should be of the same A-B-O group as the infant and of course must be free of the antigen to which the mother has been sensitized. The newborn infant does not have globulins or antibodies of its own—they are all supplied by the mother—it therefore lacks isoantibodies.

Since the infant's A and B antigens are weak and reverse typing is not informative, it is at times difficult to be sure of the infant's type. It is therefore advisable and safe to administer group O Rh-negative blood except in the rare case of erythroblastosis due to **hr′** sensitization. In emergency, the mother's red blood cells in saline suspension can be used. Exchange transfusions carry the same risk as all other transfusions, such as the danger of hyperpotassemia, hypocalcemia, citrate intoxication, overloading of the circulation, thrombocytopenia, and hypoprothrombinemia. The use of heparinized blood (instead of A-C-D blood) has been suggested, followed by neutralization of heparin with protamine sulfate and the administration of vitamin K_1 and calcium glucuronate. Large doses of vitamin K have been shown to increase the serum bilirubin level in young infants.

Hemolytic anemia due to incompatible blood transfusions

There are 2 possibilities. First, the donor's erythrocytes are not compatible with the recipient's blood, in the plasma of which are either isoantibodies or immune antibodies acting on the donor's red blood cells. This process, which is the most common occurrence in transfusion reactions, does not lead to anemia, as the relatively small number of donor's cells is rapidly destroyed. It may, however, lead to transfusion reactions, shock, and lower nephron nephrosis.

The second possibility is that the antibodies present in the donor's blood are acting against the recipient's red blood cells.

TOXIC HEMOLYTIC ANEMIAS

Toxic hemolytic anemias follow contact with foreign substances such as bacterial and viral toxins, drugs and medications, and poisons of industrial, plant, and animal origin.

Hemolytic anemia following infection

Viral infections

Although a hemolytic anemia may accompany or follow almost any viral infection, it most commonly follows in the wake of viral pneumonia. A sudden hemolytic episode may occur at the time the patient has about recovered from the pneumonia. The appearanec of the anemia is associated with a marked rise in cold agglutinins. A hemolytic anemia may be one of the first symptoms of infectious mononucleosis,[593] and it may accompany infections with the virus of measles, smallpox, and Coxsackie virus.

Hematologic findings: The anemia is usually macrocytic in type, and the peripheral blood film contains a goodly number of spherocytes, characteristic of so many hemolytic anemias and responsible for the increased osmotic fragility. The other features of hemolytic anemias also present are polychromasia, reticulocytosis, occasional siderocytes, and normoblasts.

The immune destruction may not only involve the red blood cells but also may spread to platelets and to white blood cells to produce thrombocytopenia and leukopenia. Usually moderate leukocytosis accompanies the acute hemolytic episode. Frequently autoagglutination of the patient's red blood cells can be observed.

Bacterial infections

Hemolytic anemias have been described in infections caused by hemolytic streptococci and staphylococci, such as acute and subacute bacterial endocarditis and puerperal infections. In *Clostridium* infections following injury or abortion severe hemolytic anemia may occur. Hemolytic anemias also accompany typhoid fever and cholera.

Parasitic infections

Only a relatively small group of parasites characteristically lead to the production of severe anemias, either by their action on the red blood cells or the hematopoietic system or both or by interference with intestinal absorption and production of intestinal injury (chronic blood loss). A few anemias are hemolytic.

Parasites which affect red blood cells and the hematopoietic system (hemolytic anemias) are the following:

Bartonella (Oroya fever)
Plasmodium (malaria, blackwater fever)
Leishmania (kala-azar)
Ancylostoma duodenale; Necator americanus (ancylostomiasis)
Diphyllobothrium latum
Entamoeba histolytica (amebiasis)

It must be stressed that at times infestations with other types of amebae, cestodes, or nematodes produce moderate degrees of hypochromic anemias.

Blood picture in bartonellosis (Oroya fever): The blood picture in bartonellosis, according to Groot[594] shows a rapid, progressive anemia. Erythrocyte counts of 1,000,000/c.mm. are common. The rate of decrease is rapid, with as many as 300,000 red cells/c.mm. lost in 24 hr.

The volume, diameter, and thickness of the erythrocytes are greater than normal. The mean corpuscular hemoglobin concentration is usually low but may be normal. Hyperbilirubinemia is often observed but is not constant. The bone marrow is regenerative, with large numbers of reticulocytes and normoblasts in the peripheral blood, the number of such elements being proportional to the seriousness of the anemia. Megaloblasts are often found.

Bartonellae are found in the red blood cells, the number varying. At times, 99% of the red blood cells are infected, and often it is possible to find 10-15 organisms in a single cell although these are extreme cases. Basophilic erythrocytes and macrocytes are usually less infected. Reticulocytes are seldom infected unless the number of bartonellae in the blood is very high. Normoblasts are seldom infected except in rare cases. Bartonellae are sometimes seen in the cytoplasm of monocytes.

At the beginning of the disease there is leukopenia although the number of white blood cells is normal in uncomplicated cases.

There is no typical differential count. At times either a very slight lymphocytosis is noted or more commonly polymorphonucleosis.

During the period of anemia there is an increase in young polymorphonuclear cells, etc., in the myeloid series.

The sedimentation rate is greatly increased, 100-172 mm. in 1 hr. being noted in the Westergren test.

Autoagglutination phenomena are rare.

According to Schilling this is the only acute infection which causes a severe anemia of the megalocytic type.

Malaria: The general blood changes in malaria* are as follows. Anemia is always present. It is caused both by direct destruction of erythrocytes due to the development of the parasites within them and also by toxic influences. There is oligocytosis, a lowered hemoglobin content, and a lowered color index. Polychromasia is usually marked, and coarse basophilic punctation is a frequent blood finding. In severe anemia normoblasts are found. There may be nuclear spheres, marginal granules, and other nonspecific indicators of anemia. Parasites have been observed in polychromatic and stippled erythrocytes and even in normoblasts.

Malaria pigment may frequently be found in phagocytes, usually in large monocytes (pigmentophages) although we have seen them in all 4 types of neutrophilic cells. This pigment is yellow or brown and light refracting. It is usually arranged in characteristic clumps. It originates from devoured or phagocytized parasites and is important in detecting malarial infection when no parasites are found. It is demonstrable not only in blood spreads but also in thick drop preparations.

---

*See section on parasitology.

During the attack, there is irritation leukocytosis with marked regenerative shift, neutrophilia, and decrease in the number of eosinophils. **During reduction of fever** and **shortly following this,** there are leukopenia, marked **monocytosis** and **relative** lymphocytosis, with slight eosinophilia. In **severe relapsing cases** there is a continuous stab shift. In **chronic cases,** low white counts, monocytosis, and lymphocytosis are found. The white count rises rapidly, but only temporarily, shortly after an open or latent attack. In this condition parasites are scarce. If there is a continued shift with monocytosis after treatment, it is thought to indicate recurrence. In clinically suspected malaria in which no parasites are found in the blood, one is led to the diagnosis of malaria if polychromasia is present as 2 or 3+ in the thick drop, if basophilic punctation is found, and if lymphocytes and monocytes are markedly increased, especially if quinine has already been administered.

All varieties of malaria show similar blood pictures, but acute falciparum malaria may show a higher neutrophilia with a regenerative shift to myelocytes.

In **parasite-negative cases,** the administration of 0.5-1 ml. 1% epinephrine may aid in the demonstration of the parasites. Other methods that have been used are repeated ultraviolet ray exposures and severe physiotherapy with alternating hot and cold douches. Thick drop should be examined repeatedly at intervals of several hours.

In tropical malaria, there may be both hyperleukocytosis and a left shift. The typical hemogram of **falciparum malaria** is shown in Table 251.

In the thick drop preparation there are marked polychromasia and basophilic punctation and many ring forms of *Plasmodium falciparum.*

In this disease there is severe hyperleukocytosis with comparatively high lymphocytosis and an increase in monocytes. There are no eosinophils, and there is a marked toxic polychromasia.

Blackwater fever: Blackwater fever is a hemolytic complication of falciparum malaria which leads to severe hemoglobinemia and hemoglobinuria and is subject to all previously discussed renal complications. The course is unknown but may be related to an unusual sensitivity of the red blood cells to lysolecithin.

In blackwater fever there is a marked decrease in the number of erythrocytes and in hemoglobin content. This is soon followed with improvement by a very marked regenerative normoblastic blood picture. Upon continuation or onset of new attacks, megaloblastic or aregenerative (reverse) blood pictures occur. This is an unfavorable symptom. Deaths have occurred in blackwater fever due to suppression of erythropoiesis. Parasites usually disappear temporarily during an attack of blackwater fever.

Toxic hemolytic anemias following poisoning

Lead poisoning

Hematology of lead poisoning

The effects of alimentary, respiratory, or cutaneous contact of lead with the human body lead to a definite change in the microscopic picture of the red blood cells; in the main these are the appearance of the classic basophilic punctation and a mild degree of polychromasia. These changes in the blood are the first and most striking signs of lead poisoning in man.

According to Aub and others, Laennec[595] first recognized lead anemia in man. Exposure of experimental animals to lead is followed by marked anemia. This was demonstrated in rabbits by intramuscular injection by Carcanaque and Maurel[596] and after oral administration by Key.[597]

Two causes of this anemia have been described: marked destruction of blood or a lesion in the bone marrow with consequent deficient blood formation. According to Stockman and Charteris,[598] and Raimondi,[599] bone marrow of rabbits showed a marked preliminary increase of leukoblasts with disappearance of fat, followed later by definite gelatinous degeneration. Wolff[600] described a case of severe lead poisoning in which at-

Table 251

0	0	0	18	32	20	18	12

tempts to regenerate blood were followed by deficient hematopoietic function, as seen in the bone marow. Meillére,[601] Schnitter,[602] and Sellers[603] thought that lead definitely injured both blood cells and bone marrow. Bouchard[604] and later Rauch[605] and others attributed the primary appearance of anemia to abnormal destruction of the cells in the circulation even though degeneration of the bone marrow may occur later. Evidence for this is diverse. Early lead poisoning shows hyperplasia of the bone marrow[598] with many nucleated red cells in the circulation which seems to indicate regeneration. Key[597] demonstrated that within 24 hr. after ingestion of 1 gm. lead the number of circulating erythrocytes in rabbits decreased more than 20%, with the appearance of many nucleated red cells. Meillére showed a definite increase in urinary excretion of iron, largely derived from erythrocytes, in the onset of lead anemia. J. W. S. Brady[606] in Aub's laboratory demonstrated that slow intravenous injection of lead acetate dissolved in saline caused marked hematuria and very marked increase in excretion of bile pigments from the common duct. Chester Jones[607] obtained similar evidence in human cases. He showed that both the blood plasma and bile obtained by duodenal drainage from several cases of plumbism contained very high concentrations of bile pigments. These facts indicate marked peripheral destruction of blood due to ingestion of lead.

Erythrocytes in lead poisoning show increased resistance to hemolysis in dilute saline solution. Malassez[608] reported in 1873 that not only is anemia a symptom of lead poisoning, but also that the erythrocytes are larger and more fixed than normal. Agasse-Lafont and Heim[609] found slightly increased globular resistance in lead poisoning. Von Liebermann[610] and later Orban[611] and Hayhurst[612] demonstrated this. Fici[613, 614] studied this reaction in vitro in 1921 and found that lead acetate exerts a striking effect on the hemolysis of red cells in hypotonic saline solutions, varying with concentration of lead and with temperature.

The basic defect in lead poisoning is that lead prevents the incorporation of iron into the protoporphyrin molecule so that abnormal red cells with basophilic stippling are produced. Bessis and Breton and Gorius were able to show by electron microscopy that the ferritin molecule enters the erythroblasts in lead poisoning but does not take part in the hemoglobin formation. Heilmeyer[615] classifies this anemia as a secondary sideroachrestic anemia, as this incorporated iron can be stained with Prussian blue reaction in the normoblasts as well as in the young peripheral red cells and the stippled cells. The failure to incorporate iron and the poor hemoglobin formation lead to a high serum iron level and to an increased urinary excretion of coproporphyrin III and of protoporphyrin. It may be that lead inactivates an enzyme which Goldberg[615] found in hemolysates of avian cells and which incorporates iron into the protoporphyrin ring. Other possible sites of interference with the hemoglobin synthesis are the formation of gamma-aminolevulinic acid and the protoporphyrin formation, according to Heilmeyer.[615]

In the peripheral blood the stippled cells keep company with polychromatic cells, and as shown by supravital staining there is an increased number of reticulocytes. The bone marrow shows a moderate erythroid hyperplasia, with basophilic stippling in late normoblasts.

It is believed that basophilic punctation is an effect of lead, but the presence of basophilic punctation alone does not prove the case. One must have history, clinical symptoms such as lead colic, the lead line on the gums, the finding of lead in the urine, etc.; all these serve to clinch the picture. P. Schmidt has well said that basophilic punctation is a "valuable aid before the appearance of other symptoms." There is a marked tendency today, with this disease entering into court circles, for litigants to attempt to convince juries, judges, and Workmen's Compensation Boards that the finding of basophilic punctation and polychromasia is proof positive of a case of lead poisoning or vice versa. It is fair to assume in these cases that in addition to the presence of basophilia the entire blood picture must be studied and weighed in the balance, as well as the clinical symptoms, before accurate conclusions may be drawn.

The **supravital methods of staining** are admirable for the demonstration of basophilic punctation.

The **thick drop method** of Schilling is the best method of demonstrating basophilic punctation and polychromasia in lead poisoning (pp. 1184ff). This method, originally introduced by Ross for the demonstration of malarial parasites, is now widely used in lead poisoning studies. An observation of the cen-

tral part of the drop will show the different degrees of basophilia present.

There has been some controversy as to just how to interpret this basophilic punctation in blood films and in thick drop preparations. Brueckner claims that no special significance may be attributed to basophilic punctation as compared with polychromasia and that the coarser forms of basophilic punctation are simply younger and perhaps more activated cell forms. Weight of opinion, however, seems to point to the fact that polychromasia and basophilic punctation are quite different. Polychromasia is found in marked degree in many conditions and under an endless variety of pathologic conditions, even in supposedly healthy persons who are probably under the influence of a slowly developing occult chronic illness. Basophilic punctation on the other hand is found only in very severe toxic anemias due to blood poisoning in various forms, protozoal disease, purpura, pernicious anemia, leukemia, and aplastic anemia. In other words, it is an entity due to a very definite and serious condition. When one can reasonably believe that no malaria exists, the first thought in finding a very pronounced state of basophilic punctation in the thick drop preparations or blood film would be lead poisoning or poisoning with benzol, arsenic, or with any one of the heavy metals. An objection has been raised to this conclusion by those who have studied the guinea pig experiments of Lehmann,[617-621] but one must remember that guinea pigs and man are quite different—that guinea pigs are quite sensitive and have been known to develop basophilic punctation from poor housing conditions. It must be mentioned here, however, that Konrich[622] and Lehmann[619-621] report basophilic punctation in cement workers. Jötten and Scharlau[623] failed to find basophilic punctation in workers in dusty occupations.

Whole blood lead levels of 0.09-0.3 mg.% are indicative of excessive lead absorption. Absorption is not synonymous with intoxication. (See Tables 252 and 253.)

Nonhematologic findings

Urine: Increased coproporphyrin and demonstration of intranuclear acid-fast inclusions in the sloughed renal tubular epithelium are noted.[616] In favor of excessive lead absorption is a lead level greater than 0.15 mg./L. Amounts greater than 0.2 mg./L. are indicative of excessive lead absorption. (See Tables 252 and 253.)

Summary

Lead poisoning is an acute disease characterized by symptoms involving 3 systems: the gastroenteric, hematopoietic, and nervous systems. Rarely the latter may appear to be exempt; the former 2 never are.

Acute episodes may recur and give a false appearance of chronicity. Sequelae also may persist for long periods. Signs of abnormal lead absorption are mistakenly considered to represent illness.

The cure of the disease depends on the cessation of hazardous exposure and the elimination of toxic quantities of lead from the body.

Kehoe[624] emphasizes this need for prophylaxis and decries the lack of proper preventive measures, as indicated by the great number of cases of lead intoxication that still exist. He particularly sounds a note of warning concerning the use or possible "misuse" of the newest agent in the treatment of lead intoxication—calcium disodium Versenate (ethyl-

enediamine-tetraacetic acid, EDTA). Kehoe calls attention to the long list of substances which have been used in the past to mitigate the effects of excessive absorption of lead, such as milk, ascorbic acid, and laxatives and purgatives with lemonade fortified by acid. Although the derivatives of edathamil appear to have the property of combining with lead in the soft tissues and then being excreted in the urine, it has not been established that it is lifesaving or that it can be relied upon to relieve symptoms. For the relief of colic Vigliani[625] recommends that cortisone or corticotropin be administered along with drugs which either neutralize or eliminate lead from the body. Belknap and Perry[626] recommended the combination of intravenous calcium gluconate and edathamil calcium disodium for the treatment of lead colic.

Effects of other chemicals on the blood picture

In addition to lead the blood picture may be altered by other chemical substances. Acetanilid, acetophenetidin, and other aniline derivatives produce anemia. Stengel and White[627] reported a case of chronic acetanilid poisoning and severe anemia with red cells 2,000,000 and hemoglobin 35%. There were present a great many normoblasts with many variations in size and shape of the red cells.

Arsenic in small amounts over a long period of time causes a mild stimulation of hematopoiesis. When arsenic is ingested in toxic amounts, there is a reduction in the granular leukocytes, and actual leukopenia may occur.

Arsphenamine in exceptional cases has produced an effect upon the bone marrow very similar to that seen in aplastic anemia or

*From a statistical analysis of 30 cases.

Table 254. *Differential characteristics of the anemias*

	Beginning pernicious anemia	*Advanced pernicious anemia*	*Pernicious anemia under treatment*	*Iron-deficiency anemia*
Erythrocyte count	Slightly lowered	May be as low as 1,500,000 or lower	Let it go above normal as a rule in treatment	Around 4,000,000 (except in very severe cases)
Hemoglobin	Slightly lowered	Drops quite low but not as much proportionately as drop in red count	Rises under treatment	Very low, 50-60%
MCV* cμ	Slightly over 94	100 or higher	80-94	Less than 80
Blood vol.	Low	Below normal	Below normal	Very low
MCHC† %	Slightly above 30	Slightly above 30	Greater than 30	Less than 30
Leukocyte count	Slightly lower, if any change	Leukopenia (3000-4000)	Rises back to normal	Usually higher, around 10,000
Differential	Very little significant change; any change will be shift to the right	Leukopenia, neutropenia, right shift, hypersegmented neutrophils, lymphocytosis, monocytosis; in very serious cases may see myelocytes	Gradual return to normal	Lymphopenia; frequently a stab shift
Reticulocytes	Increase; go higher after vitamin B_{12} treatment	Depends upon amount of regeneration of erythrocytes	Begins to rise on 4-5th day and continues to rise until 10th day; drops to normal	Increased
Blood platelets	Begin to decrease	Low absolute	Begin to rise	Normal
Red cells in spread	Polychromasia; tendency of erythrocytes to enlarge	Anisocytosis with macrocytes, poikilocytosis, polychromasia, basophilic punctation, hyperchromia, macrocytes, megalocytes, and nucleated red cells; may find Howell-Jolly bodies, Cabot rings, marginal granules, erythrocytes, etc.	Return to normal; increase in polychromasia; disappearance of pathologic erythrocytic findings, as a good sign	Very marked hypochromia, poikilocytosis, anisocytosis, many microcytes, diffuse basophilia; normoblasts and microblasts may at times be present
Size of red cells	Majority are normal; tendency to enlarge	Large	Return to normal	Small
Pigment content red cells	Not significantly changed	Hyperchromic (increased)	Return to normal	Decreased
Special examinations needed	Blood vol. and vol. index; reticulocyte count; blood platelet count, van den Bergh; bone marrow puncture; gastric analysis	Reticulocyte count; routine complete blood examination; same as beginning pernicious anemia	Reticulocyte counts repeatedly; repeated red cell counts and hemoglobin	Complete blood picture
Bone marrow	Increase in megaloblasts	Great increase in megaloblasts; decrease in granulocytes	Return to normal, first showing increase in normoblasts	Not needed for diagnosis

---

*Mean corpuscular volume.
†Mean corpuscular hemoglobin concentration.

Aplastic anemia	*Posthemorrhagic anemia (prolonged)*	*Sickle cell anemia*	*Chronic hemolytic anemia (idiopathic)*	*Lead poisoning*
Progressively lowering red count	Depends on severity of hemorrhage; rises as a good sign	Around 3,000,000	2,000,000-3,000,000, during attacks	2,500,000,-3,000,000
Progressively lowered; about same rate as red count	Depends on severity; usually quite low	Quite low; about same rate as red count	Drops proportionately to red cells	Very low; can go as low as 20%
80-94	Less than 80	80-94	80-94	Variable
Very low	Low	Low	Low	Low
Less than 30	Less than 30	Less than 30	Less than 30	Variable
Progressively lowered	High 10,000-15,000	High	High 25,000-30,000	Indefinite
Normal at beginning without young cells; later small lymphocytes up to 100%; never any immature white cells	Neutrophilia without shift	Shift; frequently regenerative	Very marked regenerative shift	Indefinite
Usually have none at all	Very rapid increase—depending on blood manufacture	Quite an increase	Very high	Extremely high
May completely disappear	Increase as a good sign	Very high	Very high	No significant change
Normocytic, normochromic; no change in erythrocytes noted	May see anisocytosis, marked polychromasia as a good sign; nucleated red cells in a severe hemorrhage; megaloblasts are serious	Anisocytosis, poikilocytosis, polychromasia, normocytic normochromic; nucleated red cells, basophilic punctation, Howell-Jolly bodies, Cabot ring bodies, endoglobular degeneration, target cells; sickling does not appear in film as a rule	Anisocytosis, poikilocytosis, marked polychromasia, many normoblasts, basophilic punctation, Cabot ring bodies, Howell-Jolly bodies, marginal granules, karyorrhexis, karyogenic metachromasia, megaloblasts, hypochromia, endoglobular degeneration, crescents	Marked polychromasia, basophilic punctation very coarse; may find other pathologic erythrocytes such as normoblasts, etc.
Normal	Normal, large, or may be small	Normal	Normal	Indefinite
Normal	Usually low	Normal	Normal	Indefinite
Bone marrow puncture; routine hematology serially	Reticulocyte count, serial red count, blood platelet count, hemoglobin test	Wet preparation; sometimes mix 1 drop patient's serum plus 1 drop patient's cells; sodium metabisulphite test and alkali denaturation test; electrophoretic studies	Reticulocyte count, resistance test, van den Bergh, icterus index, blood platelet, bone marrow puncture	Chemical analysis of urine and feces; reticulocyte count; thick drop
Either absence of nucleated reds or great decrease; only an occasional normoblast; may be fatty degeneration or infiltration of small lymphocytes; granulocytes disappear; may be plasma cells	Increase in normoblasts and eosinophils	Regenerative—packed with young red and white cells	Hyperplastic erythropoietic	In some cases basophilic stippling; not needed for diagnosis as rule

Table 254. *Differential characteristics of the anemias*—cont'd

	Beginning pernicious anemia	*Advanced pernicious anemia*	*Pernicious anemia under treatment*	*Iron-deficiency anemia*
Classification	Normocytic normochromic with macrocytes	Macrocytic normochromic	Return to normocytic normochromic	Microcytic hypochromic
Important points in diagnosis	Increase in size of red cells; increase in reticulocytes; response of patient to treatment with erythrocyte maturation factor (liver, vitamin B_{12})	Very low red count and hemoglobin and high color index; low white count, right shift and hypersegmentation of neutrophils; megalocytes and megaloblasts, hyperchromia; increase in reticulocytes following liver therapy; low blood platelets	Reticulocyte response to treatment; return of blood picture to normal	Tiny red cells with decreased pigment content; low color index

purpura hemorrhagica. This effect may be fatal.

Carbon monoxide produces secondary anemia. In acute poisoning, the hemoglobin changes to methemoglobin.

Nitrobenzene or shoe dye poisoning has been seen frequently. It is not at all certain that the union of the poison with hemoglobin produces methemoglobin so that the term pseudomethemoglobinemia has been devised by Peters and Van Slyke[628] for this condition. There are no changes in the morphology of the red cells.

Poisoning by benzol and related products

Benzol is a volatile inflammable fluid used in industry for cleaning printing rooms and engraving plates, in rubber cements, and in lacquers and varnishes and for many other purposes, being an excellent solvent for rubber, gums, fats, and resins.

Acute poisoning is often due to breathing excessively large amounts of benzol vapors. This may be rapidly fatal. Acute poisoning more often occurs as a result of an accident, such as the bursting of a pipe line, the overflow of a large tank, or workmen entering a tank for cleaning or repair work without using proper proctective measures.

Chronic poisoning differs from the acute type in that the benzol is inhaled in small quantities over a considerable period of time, the chief effects being observed in blood and blood-forming organs. It is a slow process, and the early stages and symptoms are not striking. Later, the symptoms increase, and if the condition is not recognized and exposure continues, serious poisoning may develop which in advanced cases may produce death.

Acute poisonings, for instance deaths in garages and poisoning in tanks, due to benzol (Marienfeld[629] and Zangger[630]) show no specific hematologic change. The subacute and the chronic benzol poisoning are suggestive of idiopathic blood diseases, and it is very difficult to distinguish them from thrombopenic diseases, such as Werlhof's purpura, agranulocytosis, aplastic anemia, panmyelophthisis, etc.

The first communication on this subject was made by Santesson[631] who reported 4 fatal cases of women workers in a velocipede factory; all 4 cases were among young women workers.

Santesson noted that with pure benzine experimentally no results were obtained, whereas with benzol (benzene), the same result was seen as in these 4 cases. In the autopsy material a study showed that severe endothelial fatty changes were responsible for the bleeding. Santesson believed that there was a central disturbance, which was first noted by Selling[632] whose clinical experimental work has been noted so often in the literature. Santesson reported 2 girls with chronic benzol poisoning, the first showing 640,000 erythrocytes and 8% hemoglobin. There was severe thrombocytopenia. In the second case there were 1,150,000 erythrocytes with 15% hemoglobin and no regenerative forms.

Benzol poisoning produces a depression of the entire bone marrow. It may lead to the various types of aplastic anemia.

HYPERSPLENISM

As has been seen in previous discussions, the spleen is always involved in hemolytic anemias, but if the splenic hemolytic activity becomes excessive and dominates the clinical picture, we speak of **hypersplenism.** Splenic

Aplastic anemia	*Posthemorrhagic anemia (prolonged)*	*Sickle cell anemia*	*Chronic hemolytic anemia (idiopathic)*	*Lead poisoning*
Normocytic normochromic	Microcytic hypochromic; normocytic normochromic	Normocytic normochromic	Normocytic normochromic	Indefinite
Entire blood and bone marrow pictures taken serially, giving picture of true aplasia	Rising red count and hemoglobin, increase in reticulocytes, high blood platelet count as good signs	75-100% of red cells sickle-shaped in wet preparation; electrophoresis shows hemoglobin-S; fetal hemoglobin increased	Entire blood picture and special tests needed; search for isoimmune and autoimmune bodies	History of exposure to lead, clinical symptoms, chemical analysis of urine and feces, +++ and ++++ polychromasia in thick drops; basophilic punctation

hemolytic anemia can be divided into 2 groups—primary and secondary.

Primary splenic hemolytic anemia

The etiology of primary splenic hemolytic anemia is unknown. It represents an exacerbation of the normal splenic function which retards the flow of red blood cells, changes their surface tension, and destroys them (see discussion of the function of the spleen). The dysfunction may find expression in increased phagocytosis or in increased hemolysis. The production of a humeral substance acting upon the bone marrow, either affecting all hematopoietic elements or only one or the other, and the release of the hypothetical toxic splenic substance may both lead to the production of a nonhemolytic splenic anemia (**dysplenism of Hittmair**).

Secondary splenic hemolytic anemia

Secondary splenic hemolytic anemia may accompany splenomegaly, irrespective of its etiology. It may thus appear as a complicating factor in congestive splenomegaly (e.g., cirrhosis of the liver), malaria, lymphomas, infectious mononucleosis, etc.

SPURIOUS ANEMIA

Before leaving the subject of anemia, it should be pointed out that it is at times difficult, on the basis of borderline laboratory data, to establish the diagnosis of an anemia. Wilson and Boyle[633] and Wiseman[634] have pointed out that a relative anemia may be caused by an increase in plasma volume. The red cell count and the hemoglobin level give the number of red blood cells and the amount of hemoglobin per unit volume. Because of its inherent error due to the trapped plasma, the venous hematocrit is usually 10-15% lower than the body hematocrit. Hemodilution may thus be interpreted as anemia, whereas in actual fact the circulating red cell mass and the circulating hemoglobin are normal. In these cases, total blood volume, plasma volume, or the erythrocytic mass should be determined by isotope methods.

DIFFERENTIAL CHARACTERISTICS OF THE ANEMIAS

Table 254 was developed at the Gradwohl School of Laboratory Technique to aid in teaching the laboratory findings in some of the anemias. It is not intended to be a complete review of the various anemic conditions, but simply a handy reference.

Chapter 65

Affections of the white blood cells

JOHN D. BAUER

An increased number of leukocytes is called **leukocytosis** and a decreased number, **leukopenia.**

LEUKOCYTOSIS

Variations may occur in the blood of the same individual even in health from day to day or at different hours of the same day. These variations may be due to an increase in any one of the elements, i.e., granulocytes, lymphocytes, or monocytes. In other words, there may be a granulocytic leukocytosis, lymphocytic leukocytosis, or monocytic leukocytosis. The purpose of the differential count is to tell what type of leukocytosis is at hand, whether it is granulocytic, lymphocytic, or monocytic. As a rule leukocytosis is usually granulocytic or neutrophilic. When we speak of neutrophilia we mean a neutrophilic leukocytosis.

Physiologic neutrophilic leukocytosis

Some authorities have spoken of digestive leukocytosis, i.e., an increase in leukocytes during digestion, but this seems to be a misconception. There seems to be a variation in the total white cell count during the day, usually a maximum of 9000 to 10,000 in the afternoon and 5000 to 8000 in the morning. These variations occur quite independently of meals. Leukocytosis has been noted in pregnancy and during menstruation and also as a result of muscular exercise. In this category we must also mention the physiologic leukocytosis of the newborn infant, of emotional disturbances (excitement, fear), and of exposure to sunlight (ultraviolet rays).

Pathologic neutrophilic leukocytosis: It occurs in the following conditions: (1) bacterial infections—infections caused by the pyogenic bacteria (pneumococci, streptococci, staphylococci, etc.), (2) metabolic disturbances—diabetic coma, uremic coma, and acidosis, (3) blood dyscrasias—hemorrhage, hemolysis, myeloproliferative disorders, and granulocytic leukemia, (4) drug administration—digitalis, mercury, phenacetin, and ACTH, (5) tissue breakdown—myocardial infarct, burns, gangrene, and tumors, and (6) allergy, vaccines, cold, and heat.

Shift of Schilling

It is generally believed that the following order of cell development occurs in the myelocytic series: (1) the myeloblast of Naegeli, (2) the promyelocyte of Pappenheim, (3) the myelocyte of Ehrlich, (4) the juvenile of Schilling, (5) the stab or band form of Schilling, and (6) the segmented cell. The last 3 are what were formerly termed **polymorphonuclear cells.** We must assume that the bone marrow is irritable or responsive or highly sensitive to an acute degree to chemotactic, humoral, and vegetative-nervous insults, that it is the primary carrier of cellular defensive forces against toxic substances in the body, especially proteogenous antigens. It was Arneth who first called attention to the left shift of neutrophilic leukocytes as a very important development of histologic changes in connection with clinical diagnosis and prognosis. All the credit must be given to him for calling attention to these nuclear changes. His work, however, is not strictly speaking a practical procedure, nor do the other types of cells which he has described in his book *(Qualitative Blutlehre)* conform to the original idea of a shift of the neutrophils. The total scheme comprises an observation of more than 80 cell species. The Schilling count divides cells as follows: basophils, eosinophils, myelocytes, juvenile cells, stab or rod cells, segmented cells, lymphocytes, and monocytes. The normal quantities are basophils, 0-1; eosinophils, 2-4; myelocytes, 0; juvenile cells, 0-1; stab cells, 3-5; segmented cells, 58-66; lymphocytes, 21-30; monocytes, 4-8. The neutrophils are myelocytes, juvenile, stab, and segmented cells, or a total of 67. He has proved that in the presence of infection there is a definite change in the proportion of these cells. In the beginning, due to the toxic impression upon the bone marrow, there is an interruption in the development from stab to segmented cells, with a consequent increase in stab cells.

To set forth the cells according to the Schilling method, construct a so-called hemogram as shown in Table 255.

Now draw a double line between the segmented and the stab cells. If the neutrophilic cells to the left of this line increase, it is called a left shift. If the neutrophilic cells to the right increase, together with a decrease or absence of these cells on the left of the line, it is called a right shift. The true right shift shows numerous hypersegmented (6 or more lobes) neutrophils.

A simple **degenerative blood picture** is a simple left shift in which the stab cells increase in number. With a continued infection and with the defensive forces of the body acting intensively under infection, this shift continues perhaps with the stab cells remaining stationary or increasing, but with the appearance of juvenile cells in the peripheral blood. At this time the appearance of juvenile cells indicates an irritation of bone marrow with regeneration. This is called a **regenerative blood picture.** If the infection continues and the patient's resistance declines, the shift advances farther to the left. If improvement ensues, the shift declines and recedes to the right. A **leukemoid shift** is a shift in which the blood picture resembles leukemia, i.e., a marked increase in myelocytes, juvenile cells, stab cells, and segmented neutrophilic cells. In this type of shift, there are no eosinophils or basophils, and the number of lymphocytes and monocytes is very low; sometimes there are none. This is a serious blood picture.

Attention is also to be called to the change in number of lymphocytes and monocytes during this infectious period. With a beginning shift to the left there is a coincident decline in lymphocytes. This decline continues until recuperation begins. With recuperation and retrogression of the shift toward the right, the lymphocytes increase. Manifestly a decline in lymphocytes indicates beginning infection, and increase in lymphocytes indicates resistance against infection. The neutrophilic regenerative shift implies a battle phase. Decline in lymphocytes indicates that the fortunes of war are with the invading organism, but with receding neutrophilia, a rising number of lymphocytes means a phase of cure. At some stage in the infectious period when resistance overcomes invasion, the monocytes show a sudden rise. This occurs often even before the shift is materially changed to the right and is termed the **phase of defense.** In the beginning of infections the eosinophils decline and often totally disappear and reappear only when the shift turns about from left to right. This is termed the **dawn of convalescence.** There is found, therefore, as a favorable prognosis, a return of eosinophils, a shift of neutrophils, changing from the left to the right, an increase in lymphocytes, and a marked increase in monocytes.

In chronic infectious conditions, a persistent high shift with low counts of eosinophils and high counts of monocytes shows a chronic simultaneous continuance of a phase of neutrophilic struggle and of monocytic defense. Thus the Schilling hemogram presents a kaleidoscopic view of infection in the blood.

We are enabled to note infection, to note susceptibility, and to note resistance. We are also able to note, very clearly, an increase in the severity of the infection and can predict, with certainty, impending death. It is in impending death that we see the flooding or liberation in which the bone marrow has finally been overcome, and the peripheral blood shows almost intact cells ordinarily found only in the bone marrow.

Broadly speaking, the Schilling hemogram

Text continued on p. 1318.

shows a biologic reaction to disease but not necessarily a specific picture for each infection. It is true that there are certain conditions of infection which give rather specific blood pictures, but it does not necessarily follow that a diagnosis of a specific infection can be made entirely by the blood picture. Certain conclusions can be drawn very accurately in many infections from the blood picture, for instance, in pneumonia, which is characterized by a hyperleukocytosis and a neutrophilia with regenerative shift. The blood findings in tuberculosis are highly interesting. With activity there is a marked shift with a decline in lymphocytes and with resistance a recession of neutrophils to the right and a marked increase in lymphocytes.

In typhoid fever there is a very interesting degenerative left shift and leukopenia. Particularly interesting is the aneosinophilia in typhoid fever. In typhus, on the contrary, we find what Schilling is pleased to term the **gay blood picture** which shows a marked increase in stab cells and quite a few juvenile cells, in other words, a regenerative blood picture, together with irritation forms and plasma cells and an increase in monocytes. This gay blood picture is also seen in measles and German measles but is less marked. It is to be noted that monocytes with an increased white cell count are conspicuous in variola but less marked in varicella, scarlet fever, and mumps.

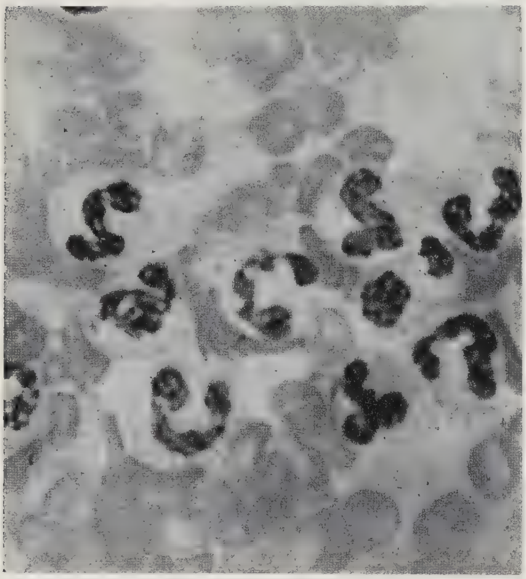

Fig. 435. Tuberculosis, blood film, showing increase in stab cells and segmented cells. (×950.)

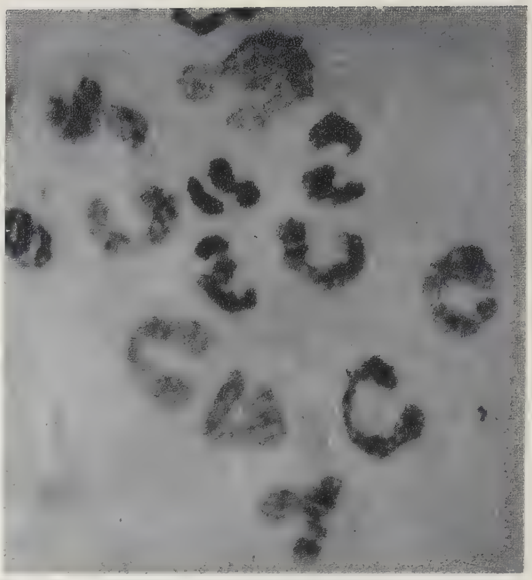

Fig. 436. Acute infection, blood film, showing increase in juvenile and stab cells. (×950.)

It goes without saying that the Schilling differential count presupposes a knowledge of the exact appearance of the different types of blood cells. It is exceedingly important to recognize the difference between a juvenile, a stab, and a segmented neutrophil. It is equally important not to confuse the lymphocytes with the monocytes.

The **nuclear shift index** (Schilling) is used particularly when the number of neutrophils in the hemogram is low. The exclusive use of the index obscures the interpretation. The nuclear shift index is the relation of pathologic neutrophils (myelocytes + juvenile cells + stab cells) to segmented forms. Normally the index is 4:64 or 1:16. Thus in a blood picture with no myelocytes, no juvenile cells, 2 stab cells, and only 18 segmented forms, the shift index is 1:9, which is a left shift.

Absolute counts of leukocytes

Absolute counts of each type of leukocyte are seldom made, but at times they are valuable to determine whether there is overactivity or underactivity of certain hematopoietic systems when the differential count alone does not show this clearly. To obtain the absolute count of each type of white cell, multiply the patient's white cell count by the % of each cell as represented in the differential count.

Normally the average white count is 7500 leukocytes. The normal differential count of Schilling is as shown in Table 256.

White cell count								
2400	–	–	–	–	–	35	60	5
Absolute cell count	–	–	–	–	–	840	1440	120

The absolute count in a normal individual, roughly, would be as shown in Table 257.

In Table 258 the absolute counts are given below the differential count.

At first glance it appears from the differential count that there has been alteration in function of the lymphopoietic system which resulted in an increase of lymphocytes. From the absolute count this is clearly seen as only a relative change. The absolute number is slightly below the normal limits.

Eosinophilic leukocytosis

An increase in the number of eosinophils or **eosinophilic leukocytosis** occurs in general in allergic states, such as certain skin diseases, asthma, and anaphylactic shock, and in infestations with animal parasites such as the hookworm and *Trichinella spiralis.* We have seen as many as 90% eosinophils in this latter condition accompanied by a marked increase in the total number of white cells. Other causes of eosinophilia are blood diseases—myelogenous leukemia, familial eosinophilia, Hodgkin's disease, polycythemia—and at times subacute infections such as tuberculosis or healing pneumonia.

In a general sense the increase in the total number of leukocytes constitutes a normal reaction on the part of the blood. In disease, however, such as leukemia, associated with an increased number of leukocytes, this increase is a primary feature and not a reaction of defense in any sense.

Basophilic leukocytosis

Myelogenous leukemia
Polycythemia vera

Lymphocytosis

- Viral infections
  - Infectious lymphocytosis
  - Mumps
  - Pertussis
  - Infectious mononucleosis
  - Infectious hepatitis
  - Viral pneumonia
  - Measles
- Bacterial infections
  - Tuberculosis
  - Brucellosis
  - Syphilis

  - Lymphatic leukemia
  - Felty's syndrome
  - Banti's syndrome
  - Infectious lymphocytosis
  - Infectious mononucleosis
- Hormonal diseases
  - Hypothyroidism
  - Hypoadrenalism

Monocytosis

- Viral infections
  - Chickenpox
  - Mumps
- Bacterial infections
  - Subacute endocarditis
  - Tuberculosis
  - Weil's disease
- Miscellaneous causes
  - Malignant tumors
  - Cirrhosis of the liver
  - Banti's disease
  - Monocytic leukemia

SPECIAL INTERPRETATION OF HEMOGRAM

In acute infections:

1. All blood pictures with beginning regenerative shifts and moderately high white cell counts are considered more favorable than those with degenerative shifts; nevertheless, rapidly increasing or very marked regenerative changes must be cautiously interpreted, especially if the white count decreases.

2. Marked signs of degeneration with decreasing white cell counts indicate a continuation of the infection.

3. Hyperregenerative and atypical hyperplastic blood pictures are serious symptoms that demand rapid removal of the cause; otherwise irreparable damage to hematopoiesis takes place and death will follow.

4. Constant aregenerative or aplastic blood pictures with low white cell counts are serious symptoms.

5. Approximately normal blood pictures and percentages must be seriously interpreted until sufficient time has elapsed to convince the **experienced** observer that the probable impending grave condition will not develop. The type of the hemogram, **determined by experience,** must always form the basis of a general estimation in any given case.

6. Marked decrease of eosinophils accompanied by rising leukocytosis indicates an **aggravated** condition.

7. Total disappearance of eosinophils (aneosinophilia*) with simultaneous marked lymphocytopenia is to be regarded as an **unfavorable** condition.

8. Constant presence of eosinophils, especially if this parallels hyperleukocytoses, means a **favorable** situation.

9. Reappearance of eosinophils (after absence from the thick drop preparation) or increase in eosinophils, with receding neutrophilia, with transition from lymphocytopenia to lymphocytosis, means a **very favorable** condition.

10. Moderately high white cell count and moderate differential change without or with slight shift and with eosinophils means a **favorable** condition.

11. The same picture in chronic conditions as an indication of a torpid cure shows a **doubtful** result.

12. Moderate or high white cell count with marked left shift, few eosinophils, and slight decline in lymphocytes indicates a condition not yet to be regarded as unfavorable.

13. Very high white cell count with marked left shift, with very young cells and marked neutrophilia, decrease of lymphocytes, and aneosinophilia suggests a **doubtful** or **unfavorable** condition, especially if these findings become more pronounced.

14. Decreasing low white cell count or leukopenia with very high neutrophilia and beginning shift to the left, lymphocytopenia, and aneosinophilia indicates a fatal prognosis.

15. Varying high white cell counts with constant hyperregenerative leukemoid or even irregular blood pictures mean a very **unfavorable** outcome.

16. Subnormal white cell counts with degenerative shift of neutrophils, lymphocytosis, monocytosis, and presence of eosinophils per se are **not unfavorable.**

17. Very low white cell counts with severe degenerative shift, neutropenia, and aneosinophilia, with only relative lymphocytosis and monocytosis, indicate an **unfavorable** state.

18. The retrogression of an existing shift (regenerative or degenerative) and of the neutrophilia or neutropenia with approach to the normal count and with reappearance of the eosinophils is to be regarded as **always** favorable.

19. On the contrary a blood picture showing a marked left shift deviating extensively from the normal count and accompanied by a decrease in or total disappearance of eosinophils is **unfavorable,** and the more extensive the deviation from the normal, the more unfavorable is the picture.

20. Marked decrease of lymphocytes in infections in which there have been hyperleukocytoses of long duration shows a **complication.**

21. Sudden decrease of lymphocytes with increasing neutrophilia and shift often with recurrent decreasing total white cell count (fall of lymphocytes) is a **very serious condition.**

22. Parallelism between lymphocytosis and hyperleukocytosis is a **favorable symptom.**

23. Transition from neutrophilia to neutropenia with receding shift, with increasing lymphocytosis, and eosinophilia is a **very favorable condition.**

24. Numerous younger or irritation lymphocytes with normal or abnormal white cell counts indicate active processes.

25. In acute infections with hyperleukocytoses, monocytosis is regarded as a **favorable** symptom, receding only in more severe affections.

26. In chronic infections, monocytosis indicates activity.

In anemias:

1. Considerable polychromasia or normoblasts without degenerative elements in the film with increasing red cell count and color index near 1.0 indicate a **favorable** condition.

2. Very marked regeneration (numerous normoblasts and erythroblasts, considerable polychromasia), and a low red cell count is to be considered a **doubtful** picture.

3. A low red cell count, decreasing hemoglobin, and decreasing color index without much polychromasia and signs of degeneration (basophilic stippling, isolated normoblasts, nuclear débris, special forms) means an **unfavorable** picture.

4. A low red cell count, leukopenia, lymphocytosis, megalocytosis, and color index above 1.0 (megalocytic or pernicious anemia blood picture) mean an **unfavorable** picture.

5. Constant low red and white cell counts without regeneration and followed by degeneration or aplasia is distinctly a very **unfavorable** condition.

BLOOD PICTURE IN VARIOUS INFECTIOUS DISEASES

Allergic states: The majority of hematologists regard eosinophilia, together with a leukopenia, as a very marked sign of allergy.

Amebiasis: In amebic dysentery there is a secondary anemia, and in severe chronic processes the erythrocyte count may drop to as

Table 260

Total white cell count	*Basophils*	*Eosinophils*	*Myelocytes*	*Juvenile cells*	*Stab cells*	*Segmented cells*	*Lymphocytes*	*Monocytes*
First day, 10,850	0	12	0	0	5	48	33	2
Second day, 10,450	0	12	0	0	5	55	23	5

low as 2,000,000, with a still greater reduction in hemoglobin. There is hyperleukocytosis and a marked left shift. Eosinophilia is insisted upon by some and denied by others. It is a general belief of hematologists that the presence of eosinophilia indicates infestation with intestinal worms as a complication.

When amebic abscess of the liver supervenes, there is no special increase in leukocytes.

Appendicitis: The hemogram is of some assistance in elaborating the diagnosis of appendicitis; *one is in no way able to predict from the hemogram alone the exact degree of pathology which will be found at operation or after microscopic study.* Some clinical pathologists and surgeons attempt to draw conclusions of too refined a character from the hemogram in the presence of a disturbance in the lower right quadrant. We wish to emphasize that the study conducted by Gradwohl,* together with other experiences, would cause us to hesitate to draw any conclusion other than the presence of inflammation of the appendix from any given hemogram. We do, however, acknowledge that a falling total count and an increased left shift is a prime indicator of a probable rupture, with severe peritonitis and possibly a fatal outcome. It can be noted that, first, there may be an irregular fever in all types of appendix inflammation; second, there is a difference in the degree of symptoms; third, there is very little difference in the height of the white cell count and in the left shift in most cases whether they are so-called acute or ruptured appendicitis or chronic appendicitis with acute exacerbation. The distinction, if any, may possibly be a more pronounced left shift, but this is not a sufficient basis upon which to make an absolute differentiation. The blood picture in the chronic cases with intermittent flare-ups shows leukocytosis, together with a left shift, although this leukocytosis in a general way may not be as high as that commonly found in the acute conditions. Attention must also be called to the fact that in the case of fecal impaction without much pathologic disease in the appendix wall, there is a mild but definite left shift.

Bubonic plague: There is neutrophilic leukocytosis, around 40,000. Platelets are increased. There is a very marked left shift.

Coccidioidal granuloma: There is moderate leukocytosis, usually around 15,000. Eosinophils are sometimes above normal. Riseman and Ahlfeldt[635] reported a case with 22,000 white cells and 12% eosinophils. There is a secondary anemia.

Diphtheria: There is characteristic leukocytosis in diphtheria. With the injection of diphtheria antitoxin, there is a rapid decline in the number of leukocytes. Schlessinger[636] investigated leukocytosis in experimental diphtheria in animals. After injection of diphtheria bacilli, he noted leukopenia together with a decrease in lymphocytes, and then came an increase in leukocytes. Heim[637] claims that leukocytosis runs parallel with the intensity of the infection. Others note an absolute and relative increase in neutrophils, together with a decline in lymphocytes in the beginning of the disease.

Encephalitis lethargica: This is characterized by a slight increase of leukocytes, with a moderate degree of anemia. There is a slight left shift. Some authors have reported leukopenia and also eosinophilia during the convalescent period. The type of encephalitis that occurred in St. Louis in 1933 showed slight leukocytosis and a left shift.

Erysipelas: There is a hyperleukocytosis with a marked regenerative shift to the left. Total neutrophils may attain a figure of 90.

Hansen's disease: The predominant feature of the blood in Hansen's disease is an anemia. Leukocytes are not increased, and eosinophilia is not common.

Influenza: Influenza is characterized by leukopenia with a left shift. A typical hemogram is shown in Table 261.

Measles: In measles there are no characteristic changes in the hemoglobin content value or the count of the red cells. At the beginning of the disease there is neutrophilic

---

*Gradwohl, R. B. H.: J. Missouri M. A. **30:**123, 1933.

leukocytosis followed rapidly by neutrophilic leukopenia. The leukocytes appear during incubation, and the leukopenia is seen at the time of eruption. Leukopenia is almost continuous, the lowest count recorded being 2400 during the height of the disease. Usbeck found leukopenia in the beginning inconstant. Hecker found, during the incubation period at the time of the appearance of the Koplik spots, leukopenia as well as relative and absolute lymphocytopenia with a left shift, and a decrease in eosinophils. In the second half of the period of incubation, there is an increase in lymphocytes and a decrease in neutrophils.

In the exanthematous period there is leukopenia and an absolute and relative decrease or absence of eosinophils. This typical blood picture was found 12 times in 41 cases examined. In recrudescence there are leukocytosis and relative lymphocytosis and eosinophilia. There is not a left shift.

With complications, such as pneumonia, otitis, etc., we may find leukocytosis, neutrophilia, and a left shift. The blood platelet count at the beginning of the exanthematous period is decreased to 100,000.

During the eruption there is a marked left shift with predominance of young forms. There are plasma cells and the usual gay blood picture of Schilling.

Paratyphoid A and B infections: Paratyphoid A and B show a reduction, possibly to ½ million, of red cells with a lowered hemoglobin content. The leukopenia is not as pronounced as it is in typhoid fever. The left shift is about the same.

Parotitis epidemica (mumps): Lehndorf[638] reported the blood pictures of 14 cases of mumps in adults. Leukocytes were normal. Lymphocytes were increased 30-65%. Two % plasma cells were found. Neutrophils were decreased, as were eosinophils.

Wiese's[639] findings in 115 cases of mumps from the ages of 5 to 15 yr. are given in Table 262 (no changes in the hemoglobin and red cell count).

There are a marked left shift and lymphocytosis together with leukopenia in the beginning of the disease.

Pneumonia: In pneumonia there is marked hyperleukocytosis, together with a very severe left shift. The total count may exceed 35,000, especially in children, when it may be 50,000. This is marked neutrophilic leukocytosis with a left shift. Occasionally myelocytes may be found during the height of the disease. The leukocytosis occurs very soon after the beginning chill and remains until the crisis occurs. With the crisis, there is a return of eosinophils and an appearance of monocytes—the so-called dawn of convalescence. One is accustomed to think of severe hyperleukocytosis in pneumonia as a favorable symptom and the absence of leukocytosis as a very unfavorable symptom. If leukopenia is found in bacterial pneumonia, the prognosis is very grave. There is very little change in the red cell picture and only a very slight reduction in the erythrocytes and hemoglobin. Blood platelets are increased, and the sedimentation rate is markedly heightened.

Pertussis: In pertussis there is leukocytosis, sometimes as high as 40,000 or higher. The

younger the child, the more outstanding is the leukocytosis. This leukocytosis is practically a lymphocytosis. In 24 cases in the catarrhal stage, there was an average of 20,000 white cells, of which 32% were neutrophils and 66% were lymphocytes. The highest leukocytic and lymphocytic figures are found during the paroxysm of the disease. Complications by streptococcus, pneumonia, or staphylococcus do not seem to influence the count. In a typical pertussis case Thiemann found 42,000 leukocytes, with 76% lymphocytes and 19% neutrophils.

There is a left shift of the neutrophils in either the catarrhal or paroxysmal stages. Count of the eosinophils is not changed. The monocyte count is normal at first but becomes slightly elevated later. In complications there is likely to be a left shift in the neutrophils without any change in the lymphocytes.

Psittacosis: In psittacosis there is an absence of leukocytosis at the beginning of the infection. Leukopenia is present in a small number of cases. When the disease is at its height, there is a shift to the right of the neutrophils, accompanied by a distinct fall in lymphocytes. As the patient improves, normal distribution of the blood cells follows. There is a distinct acceleration of sedimentation time at the beginning of infection.

Scarlet fever (scarlatina): The so-called gay blood picture with increase of eosinophils is characteristic of scarlet fever. Most cases show a marked neutrophilic leukocytosis. Values of 20,000/c.mm. in severe cases are often found. In milder cases, the count is around 10,000. The white cells are increased coincident with the exanthematous eruption. With decline in fever the white cells gradually decline. In this disease we find persistent leukocytosis, sometimes for a long time after the decline of the fever. The count is usually back to normal at the time desquamation is finished.

Increase in the eosinophils begins shortly after the onset. In the beginning of the disease, the increase is confined to the neutrophils. The neutrophils show changes in the nuclear structure, with degeneration in the cytoplasm and the formation of vacuoles, and basophilic clumping, the so-called Döhle inclusion bodies. (For further details see remarks on toxic granules, p. 1177.) They are plump and usually heavily stained granules. Monocytes are numerous. There is a relative and absolute increase.

Roth claims that there is a sudden increase of neutrophils in scarlet fever and then a gradual rise to higher levels, with postinfectious lymphocytosis without an increase of monocytes. Plasma cells are sometimes found, according to Ciuca,[640] and the count may be as high as 17%.

The most interesting feature of the scarlatinal blood picture is the eosinophilia. In the first 2 days, the eosinophil count is low, increasing after the second or third day of exanthematous eruption.

According to Türk[641] scarlatina may show as many as 14% eosinophils. Naegeli found as many as 22%. He has one record of 25% in a leukocyte count of 10,000.

The maximum period for eosinophilia usually occurs at the end of the first week. In very severe and in lethal cases, the eosinophilia is absent, according to Ambrus,[642] Georgescu,[643] Markovitch,[644] and Ketschetkoff.[645] Naegeli reports that on the third day of a case of severe septic scarlatina he found only 0.5% eosinophils; on the fourth day the case ended fatally. Heubner and Roth[646] also reported cases of septic scarlatina without eosinophilia.

Basophilic cells also have been found increased in this disease sometimes as high as 4%. A few myelocytes have been found, 3% in a total count of 16,000 having been recorded.

There may be severe secondary anemia in scarlatina. Occasionally nucleated red cells have been observed.

Tuberculosis: Beginning tuberculosis shows an increased total white cell count and a distinct left shift.

The red cells show a slight reduction in total numbers in tuberculosis, except in the terminal stages.

The count of the white blood cells is important in tuberculosis. The discovery by Sabin et al.[647] of the relationship which exists between the monocyte of the circulating blood and the epithelioid cell of the tubercle forms the basis for the increased interest in the cellular mechanism of this disease. Cunningham et al.[648] first showed the importance of the **monocyte-lymphocyte** ratio as obtained from differential counts of the circulating blood. Progressive tuberculous lesions showed a gradually increasing monocyte count and a decreasing lymphocyte count, whereas regressing lesions were accompanied by a reversal of these relationships, i.e., by a lowering of the monocyte-lymphocyte index in the blood (normal is 0.33). Qualitative changes in the monocytes, with the appearance of epithelioid cells in the peripheral blood, are quite as significant as the quantitative changes just mentioned. Medlar[649] has emphasized the importance of the neutrophilic leukocytes in appraising the incipiency and extent of caseation and cavitation in tuberculous foci.

Wiseman[650] re-evaluated certain qualitative changes in lymphocytes with reference to age and maturity which when applied to the study of these cells in tuberculous cases further aids in the analysis and prognosis of the disease. Wiseman found the normal average lymphocyte formula to be 5% young basophilic types, 45% mature moderately basophilic forms, and 50% old, faintly basophilic lymphocytes. In tuberculosis the increase in young immature forms denotes an additional strain placed on the lymphatic tissues. It has been recognized for a long time that resistance to tuberculosis is associated with relative lymphocytosis, but it is essential that the lymphocytes be relatively mature to serve their function. Thus in known tuberculosis patients, if the total lymphocyte count is relatively low, with a degenerative rather than a regenerative shift to the left, the prognosis is grave, even though the monocytic-lymphocytic index may not be markedly increased.

In tuberculosis there is a shift of the neutrophilic leukocytes, with an increase in the stab cells. With increasing severity there is a regenerative blood picture. The commonest type, however, is the degenerative picture. Progressive cases show falling lymphocytosis. Cases doing well show normal lymphocytes or an increase. Eosinophils are usually present, and their presence or absence is of little significance. The same is true of basophils. Allusion has already been made to the ratios between the monocytes and lymphocytes.

Tularemia: The blood picture in tularemia is neutrophilia with a left shift.

Typhoid fever: Typhoid fever is characterized by leukopenia down to 3000-5000/c.mm. and a left shift. Eosinophils disappear at the beginning of typhoid fever. They do not reappear until the third week of the infection.

Certain definite prognostic facts in typhoid fever may be read from the hemogram as follows:

1. A very few eosinophils in the first stage speaks for a mild infection. The reappearance of the eosinophils in the third stage of typhoid fever is a good prognostic factor. A relatively high neutrophil percentage is found in the prodromal stages; as the disease becomes more pronounced, there is neutropenia plus lymphocytosis. Supervening neutrophilia is indicative of a possible complication, especially if there is a regenerative shift. A return of lymphocytes or a regression of the shift in the third stage is a favorable symptom.
2. Unfavorable symptoms are a continued leukopenia and an increasing left shift.

The mechanics of the lowered white count in typhoid fever is undoubtedly a toxic insufficiency of the bone marrow. Studies of the bone marrow in this disease show very few myelocytes and many myeloblasts.

Typhus: In typhus the hemogram is as given in Table 263.

There are many plasma cells. Schilling calls this picture the gay or the colorful blood picture.

Naegeli is inclined to think of slight leukocytosis in typhus. He cites 17 cases by Slatineano with 14,000 leukocytes and 13 cases by Cazeneuve with from 10,000-30,000 leukocytes. Rothacker does not think that the leukocyte count is ever higher than 14,000.

The diagnostic symptoms in the blood picture of this disease are the gay blood picture, with a left regenerative shift. Eosinophils do not disappear quite as rapidly and uniformly as they do in typhoid fever. Cazeneuve places considerable diagnostic importance upon the appearance of myelocytes (2-12%) in typhus.

Most authorities speak of a marked decline in the number of red cells in this disease, accompanied by a hemoglobin drop, sometimes down to 52%. Dychno[651] describes red cell resistance figures up to 0.32-0.36%.

Varicella: There is no change in the hemoglobin and the red cells in this disease. Arneth found during the eruptive period of the disease in a 2 yr. old boy a white cell count of 6000 and with recovery a restitution to normal figures. There is a left shift at the begin-

ning, but this rapidly disappears. Nobecourt and Merklen reported 15 patients, ages 1 to 5 yr., without any characteristic changes.

In the suppurative stage there is a characteristic left shift which decreases with the decline of suppuration. So far as the blood platelets are concerned, they decrease with the beginning of fever and increase with the decline of fever.

Variola: The blood picture of variola is characteristic and constitutes a very important link in the diagnostic chain. We find early in the disease a marked regenerative shift (on the fourth day), as shown in Table 264, together with a marked hyperleukocytosis. We are also likely to find many plasma cells, 11% plasma cells having been recorded. According to Schilling there is a marked left shift and an increase in monocytes—not only the normal monocytes are increased, but there also are abnormal large juvenile forms of monocytes. Fischer has described myelocytes and large lymphocytic irritation forms in this disease.

Viral or atypical pneumonia: In contradistinction to bacterial pneumonia, viral pneumonias have leukopenia with a left shift. However, there generally is present moderate lymphocytosis. Owrens et al.[652] showed that in some cases there may occur a very marked absolute and relative lymphocytosis associated with leukocytosis up to 20,000. During this period, such cases may be confused with acute infectious lymphocytosis and with acute infectious mononucleosis. However, the pathologic lymphocytes of acute infectious mononucleosis are either absent or present in only small numbers. The heterophil antibody test is negative.

LEUKOPENIA

Leukopenia is a reduction in the number of leukocytes in the circulating blood below 4500/c.mm. The leukopenic state has been reproduced experimentally and occurs clinically quite frequently. It has been the subject of much investigation.

Lawrence[653] lists 5 possibilities as playing a role in the pathogenesis of leukopenia:

1. Diminished manufacture of white blood cells. This may be the result of (a) simple inhibition, (b) maturation arrest, (c) aplasia of the bone marrow, and (d) infiltration of the bone marrow with foreign cells.
2. Increased utilization of white blood cells. This may occur when large quantities of cells are poured into infected areas, such as in empyema, or when large numbers of cells are lost through normal channels, such as the gastrointestinal tract, the lungs, the spleen, or the liver.
3. Increased rate of destruction in the peripheral blood. This may be due either to abnormal white blood cells or to abnormal substances in the blood channels which cause destruction of the white blood cells, e.g., leukocyte antibodies and substances resulting from sepsis.
4. Redistribution of the white blood cells in the vascular channels, such as occurs in anaphylactic shock following exposure to foreign proteins. Masses of leukocytes are then retained in the lung, liver, and spleen.
5. Hormonal leukopenia. This occurs as a result of hypersplenism, stress, and the administration of ACTH.

Although this summary of the causes of leukopenia is apparently all-inclusive, it is difficult to fortify all these conditions with experimental or clinical facts.

It is thought that viral infections, typhoid fever, malaria, and overwhelming infections can be cited as examples of simple inhibition; nevertheless, there is a possibility that other mechanisms enter into the causation of leukopenia in these conditions. Viral infections, such as influenza, dengue, viral hepatitis, viral pneumonia, acute poliomyelitis, and vaccinia, are almost always accompanied by leukopenia. It is rather interesting that such a large number of viral infections is associated with a low white blood cell count, which is in sharp contrast with the leukocytosis which occurs in most bacterial infections. It might be worthwhile philosophizing that in viral infections leukocytes are not a predominant defense mechanism and are therefore not called upon to handle the infection. Typhoid and malaria (after the attack) are given as examples of simple inhibition, but it is rather interesting that both of these diseases are associated with splenomegaly, a condition which is associated with leukopenic states, perhaps due to some form of hypersplenism.

Maturation arrest of cells of the myelocytic series is most frequently associated with agranulocytosis due to drug intoxication, such as from the sulfonamide drugs. In these instances some hypersensitivity phenomenon has been implicated as the modus operandi of the maturation arrest phenomenon.

Although leukopenia may be seen at times in aplasia of the bone marrow, it is rather surprising how infrequently this phenomenon is associated with rather marked aplasia of the bone marrow in various clinical conditions. Such aplasia may be due to idiopathic states or may result from therapy which destroys the bone marrow. Such therapy includes radiation, both in the form of x-ray and radioactive isotopes, and may be associated as well with severe nutritional deficiencies.

Infiltration of the bone marrow with tumor cells of various kinds includes metastatic carcinoma, multiple myeloma, and other diseases, but a simple explanation is not forthcoming for the leukopenia associated with such states. The relatively simple explanation of overcrowding by tumor cells is hardly acceptable.

When we speak of diminished manufacture of white blood cells within the bone marrow as a cause of leukopenia, we must also take into account the delivery of cells into the peripheral blood. This is a subject about which at the present time we know practically nothing. There are numerous examples of bone marrow overcrowded with white blood cells and with a peripheral leukopenia and vice versa.

Palmer and associates[654] have been able to reproduce in rats a disorder closely resembling the clinical syndrome in man to which the term secondary hypersplenism has been applied. This syndrome, produced by the injection of methyl cellulose in rats, presents a picture characterized by splenomegaly, hyperplasia of the bone marrow, and leukopenia, among other things. In their animals, if splenectomy was performed prior to the injection of the methyl cellulose, no leukopenia occurred; in fact, a splenectomy type of leukocytosis appeared, whereas in animals injected with methyl cellulose and developing the full syndrome, leukopenia was evident. They point out the prophylactic role of the splenectomy in their animals and also state that infiltration of the bone marrow by methyl cellulose-containing macrophages is not the explanation for the pathogenesis of these changes. They particularly point out that pancytopenia failed to develop in splenectomized animals, even though there was an equal degree of infiltration of the bone marrow by the methyl cellulose, and the bone marrows of the animals given the methyl cellulose were characterized by hyperplasia of the blood-forming tissue.

No discussion of the subject of leukopenia could be complete without invoking the present interest in immunologic processes as a cause of anemia, thrombopenia, and leukopenia. Well-documented experimental and clinical studies have been numerous in the literature concerning the role of immunologic abnormalities relating to red blood cells, hemoglobin, and platelets. However, fewer reports are present concerning leukocytes. Kissmeyer-Nielsen[655] carried out transfusion experiments to prove the presence of a leukopenic factor in the blood of patients with leukopenia, and he believed that he could demonstrate such relationship.

In speaking of the leukopenic phases of leukemia, most observers are referring mainly to granulopenia or neutropenia. In acute agranulocytosis unquestionably the disappearance of the granulocytes is due to the failure of the myeloblasts or the myelocytes to mature into adult cells. It has been found that the bone marrow varies according to the stage of the disease, but at times myeloblasts may be the only representatives of the granulocytic series.

Only a few minutes are required to cause the disappearance of granulocytes from the blood after a small dose of aminopyrine in some patients. Vejlens, in Norway, found that certain hydrophil colloids, such as globulin, which produce leukopenia when injected intravenously, do so by causing the white cells to take up a marginal position in the venules of internal organs such as the liver, spleen, and omentum. This is really a type of leukocytic shock because the leukocytes are temporarily out of the circulation. This may be caused by gelatin, globulin, and fibrinogen.

Piney[656] called attention to chronic neutropenia which falls in the diminished manufacture group. Here the only clinical syndrome is apparently causeless fatigue or lassitude, with a granulopenia of less than 200 cells/c.mm. In these cases, treatment, including pentnucleotide, fails to influence this neutropenia although Piney's patient recovered after receiving Hepatex T.

With respect to the fifth possibility, redistribution in the body as a whole, the mechanism that is responsible for the distribution of the white blood cells between the tissues and the vascular channels is unknown. Lawrence gives as the best illustration of this the so-called aleukemic leukemia. In this condition there may be leukopenia, and yet the various tissues in the body may be filled up with white blood cells. That this may occur in other conditions is a distinct possibility.

Many of the facts relating to the cause of leukopenia have yet to be developed.

In summary, leukopenia may be classified (1) according to the location of the defect and (2) according to the main type of cell involved.

Classification

- According to location of defect
  - Diminished formation of leukocytes due to bone marrow defect
    - Radiation effects
    - Effects of drugs and poisons
    - Aplastic anemia
  - Maturation arrest of white blood cells
    - Agranulocytosis
  - Excessive destruction of white blood cells
    - Autoimmune antibodies
- According to main type of cell involved
  - Neutropenia
    - Bacterial and parasitic infections
      - Malaria
      - Typhoid fever
      - Brucellosis
      - Septicemia (overwhelming)
    - Viral infections
      - Measles
      - Hepatitis
      - Poliomyelitis
      - Mumps
    - Blood diseases
      - Aplastic anemia
      - Agranulocytosis
      - Myelofibrosis
      - Pernicious anemia
      - Hypersplenism
    - Toxic agents
      - Radiation
      - Cytotoxic drugs
      - Immune antibodies
    - Hormonal diseases
      - Addison's disease
      - Thyrotoxicosis
      - Acromegaly
  - Eosinopenia
    - Infections before recovery stage
    - Blood diseases
      - Infectious mononucleosis
      - Hyposplenism
      - Aplastic anemia
      - Pernicious anemia
    - Hormonal influences
      - Cushing's syndrome
      - ACTH administration
      - Epinephrine administration
      - Insulin administration
      - Thyroxin administration
      - Stress
  - Lymphopenia
    - Infections
      - Tuberculosis
      - Weil's disease
    - Diseases of lymphatic system and blood
      - Hodgkin's disease
      - Lymphosarcoma
      - Immune antibodies
      - Agranulocytosis
      - Aplastic anemia
      - Bone marrow depression due to radiation effects and effects of drugs and poisons
    - Hormones
      - ACTH
      - Epinephrine
      - Cortisone
      - Insulin

AGRANULOCYTOSIS

This disease has been called by various names. Agranulocytosis was the name given to the disease by Schultz,[657] who first described it. Schilling called the disease malignant neutropenia. It has also been called angina agranulocytica, stomatitis gangrenosa myelophthisica, malignant leukopenia, and sepsis with granulocytopenia.

Definition

Agranulocytosis is a blood disease characterized by the disappearance of neutrophils from the peripheral blood or by a marked diminution. In the pure form of the disease there are no changes in the red blood cells or in the platelets, but there are forms in which the granulocyte-depressing influence also embraces the red cells and the platelets.

Classification

Classification of agranulocytosis is according to whether the disease is congenital or acquired.

- Congenital forms
  - Chronic benign granulocytopenia in childhood
  - Infantile genetic agranulocytosis
  - Neonatal agranulocytosis (transient)
- Acquired forms
  - Toxic-allergic immuno-agranulocytosis
  - Cyclic agranulocytosis
  - Symptomatic agranulocytosis
  - Hypersplenic agranulocytosis
  - Bone marrow depression or obliteration

Neonatal agranulocytosis

Neonatal agranulocytosis is acquired in utero due to transplacental transfer of antileukocytic antibodies. This disease thus forms a bridge between the congenital forms and diseases in the other classification, the acquired forms.

Immunoagranulocytosis (toxic-allergic agranulocytosis)

White blood cells are antigenic. Not only can each type of white blood cell, e.g., neutrophil, lymphocyte, and monocyte, act as an antigen, but also the various parts of each white cell can give rise to antibody formation, e.g., cytoplasm, nucleus, mitochondria, etc.[658, 659] In addition, white blood cells also contain group antigens A and B similar to the erythrocytic antigens. It is interesting to note that experimentally only anticytoplasmic antibodies lead to leukopenia, with the exception perhaps of the so-called L.E. factor. The administration of such an anticytoplasmic antiserum leads to rapid disappearance of the granulocytes in the peripheral blood and to stasis and destruction of the leukocytes mainly in the pulmonary capillaries, but also to some extent in the spleen and liver. The destruction is probably brought about by the same forces that affect sensitized red cells: agglutination, phagocytosis (opsonins?), and lysis (complement utilization?). It has been known for a long time that anaphylactic shock produces leukopenia which is thought to be due to white cell stasis, destruction of leukocytes in the lung capillaries, and the release of heparin, an antileukocytic substance. Experimental allergic reactions (not anaphylactic) fail to produce these events.

Agranulocytosis following administration of certain drugs

One of the most challenging problems in pharmacology is the production of leukopenia following the administration of drugs. The list of drugs capable of producing agranulocytosis in a sensitive patient is almost unending, as can be seen from a quick glance at the list of potentially dangerous drugs published by the American Medical Association.[660]

The condition has been known to follow arsenic and bismuth injections. Madison and Squire[661] reported 13 cases in which they thought this condition was due to the use of benzene chain derivatives. Watkins[662] discussed the role played by barbiturates and aminopyrine in the causation of neutropenic states.

Von Bonsdorff[663] reported 3 cases with agranulocytosis. In 2 cases it was virtually certain that medication with aminopyrine was the cause, and it was probably the cause in the third case. In some persons a few small doses of aminopyrine produce granulocytopenia, whereas in others it appears suddenly some time after large doses of the substance have been administered, without causing disturbance at the time of administration. This shows that therapeutic doses of aminopyrine in sensitive persons may have a detrimental effect on the general condition and on the hematopoietic organs. The action on the granulocytopoietic apparatus is stimulating as well as inhibiting. The total number of granulocytes decreases, but the immature and young forms increase. In some instances leukocytosis may follow. Aminopyrine influences the organs that produce the monocytes and lymphocytes as well as the erythrocytes. The changes disappear spontaneously when medication is discontinued. However, it may be assumed that the continuous use of aminopyrine may eventually cause grave clinical symptoms. Animal experiments proved likewise that the administration of aminopyrine or of related substances may eventually impair the hematopoietic organs and lead to leukocytosis, leukopenia, or anemia.

Kracke[664] pointed out that coal tar products may be responsible for this disease. In one case he claimed that acetophenetidin was probably responsible for this disease. There have been attempts made to differentiate between the etiology of the acute cases and the so-called chronic cases. Roberts and Kracke[665] were impressed by the increasing number of acute fulminant cases and the large number of so-called chronic cases. They claimed that the acute cases represent a very small percentage of the total number of individuals whose blood count is depressed to some degree. Kracke and Parker[666] described the effects of drugs containing the benzene ring on agranulocytosis. They stated that a certain percentage of the cases are due to arsphenamine and a certain percentage to gold salts and perhaps other chemicals, leaving a large group of the idiopathic type with an unknown etiology.

It has been proved that drugs may affect the bone marrow in certain peculiarly sensitive individuals. For instance, purpura following quinine administration has been observed. Benzene administration may be followed by aplastic anemia. Krumbhaar noticed profound leukopenia and marked changes in the bone marrow from mustard gas poisoning.

Pathophysiology of drug-induced agranulocytosis: In a sensitive individual the agranulocytosis-inducing drug acts as a hapten which combines with serum protein to form an antigenically active complex. Antibodies directed against this drug-protein complex are adsorbed onto the granulocytes. When these sensitized cells are exposed to the original drug, they are destroyed in the lung, liver, and spleen. The bone marrow responds to the peripheral cell loss by myeloid hyperplasia and the release of immature granulocytic cells. If the marrow stimulation persists, bone marrow exhaustion may ensue, with resulting complete disappearance of granulocytes. Bone marrow failure can also be explained by assuming that the bone marrow rather than the peripheral cell is the main shock organ, the target for the antibody activity. Although the existence of antileukocytic antibodies has been definitely proved, there is still some difficulty in explaining their specificity (see discussion of autohemolytic anemias).

Agranulocytosis accompanying bacterial and viral infections

The same process of autoantibody production that has been described as being responsible for the production of acquired hemolytic anemias also plays a part in the pathogenesis of agranulocytosis in bacterial and viral infections. The added factor of toxicity must also be taken into consideration. Agranulocytosis may be seen in viral pneumonia, infectious mononucleosis, hepatitis, brucellosis, and measles.

Symptomatic agranulocytosis

Agranulocytosis may be one of the manifestations of lymphomas, leukemias, macroglobulinemia, lupus erythematosus, rheumatoid arthritis, etc. In these diseases the dysproteinemia may be partially responsible for the immune mechanism, as it is in the production of symptomatic hemolytic anemias.

Cyclic agranulocytosis (cyclic neutropenia)

This is a rare disease that occurs in infancy and childhood in which the circulating granulocytes disappear for about 10 days from the peripheral blood at intervals of 3-4 wk. Depletion of marrow granulocytes precedes the peripheral changes.

Symptoms are variable and tend to mimic those seen with agranulocytosis, consisting of stomatitis, acute lymphadenopathy, fever, and fatigue. Sore throats and joint pains may be present. Physical findings are not unusual except for the lymphadenopathy and occasional mild splenomegaly. The white blood cell count varies between 2000 and 4000/c.mm., with neutropenia from 0-16%.

Agranulocytosis due to hypersplenism (splenic neutropenia)

The splenic hyperactivity may be primary or secondary due to splenic enlargement, as seen in cirrhosis of the liver (Banti's disease), portal hypertension, lymphomas, Gaucher's disease, Felty's syndrome, etc. In the etiology a bone marrow-directed hormonal factor may be involved, or hypersequestration of the peripheral cells may take place in the splenic sinusoids.

Chronic agranulocytosis

The name is self-explanatory. The disease may persist for months or years and may or may not be accompanied by clinical manifestations.

Laboratory investigation of agranulocytosis

The disease usually begins with a sore throat of sudden onset. Occasionally, however, there is a history of long-continued sore throat. There are fever and prostration. Examination of the blood will usually suffice to clinch the diagnosis. The hemoglobin and red cell count estimations are normal. Occasionally there may be an unexplained severe anemia, but this is not common. The number of blood platelets may be normal or decreased. The white blood count is the most characteristic feature of the disease.

White blood cell count and differential count

There is a diminution of the total number of white blood cells, which may be down to 1000. We have seen cases with counts as low as 500. The lower the total count, the fewer are the granular elements—so much so that finally no granulocytes are seen at all in the blood spread. The differential count shows complete disappearance of neutrophilic leukocytes with relative lymphocytosis and occasionally monocytosis. In fatal cases the number of white cells remains low and shows a progressive decline. Gradual increase in the percentage of neutrophils and in the number of leukocytes is a favorable symptom. The nuclei of the neutrophilic segmented cells are blurred. The neutrophilic granules appear basophilic and coarse. These are the toxic granules first described by Cesaris-Demel.

Examination of bone marrow

The bone marrow shows variable pictures in different types of agranulocytosis. The picture may be hyperplastic, aplastic, or reticuloendothelial in type. The usual type is aplastic, which has a serious prognosis. A hyperplastic type probably indicates a favorable outcome. In the aplastic type the bone marrow shows many lymphocytes, reticulum cells, and plasma cells. In the hyperplastic type, there are numerous promyelocytes, occasional myeloblasts, and at times metamyelocytes in milder cases. A few of the promyelocytes or myeloblasts are abnormally large and at times binucleated. Regeneration originates in these forms. These abnormal forms point to an abnormality of the cell division rather than to a maturation arrest as the etiologic mechanism of agranulocytosis. The more mature the bone marrow cells are, the better is the prognosis.

Roberts and Kracke[665] saw degenerative myeloblasts in cases of agranulocytosis reported by them. There is a type of reticuloendothelial change in bone marrow in some cases of agranulocytosis which shows marked hyperplasia of the reticuloendothelial system in addition to the presence of lymphocytes and plasma cells in the bone marrow. These reticuloendothelial cells are clasmatocytic in appearance. The erythropoiesis and the thrombocytopoiesis are not involved.

The blood picture that is typical of this disease shows a differential count of, let us say, 90% lymphocytes and 10% monocytes with no granulocytes whatsoever.

Test for leukoagglutinins[667]

Principle: A suspension of leukocytes from normal donors is incubated with the serum to be tested and then examined for agglutination.

Reagents: Inactivate all sera (control serum, group O serum, and unknown serum) at 56° C. for 30 min.

1. Leukocyte suspension.
   - (a) Defibrinate 20 ml. blood from healthy donors (no history of transfusion!) with glass beads in an Erlenmeyer flask.
   - (b) To 4 parts defibrinated blood, add 4% polyvinylpyrrolidone (PVP) solution, mix, and allow to sediment at 37° C. for about 1 hr.
   - (c) Remove the leukocyte-containing supernatant PVP-serum mixture.
   - (d) Count the leukocytes in this mixture and add inactivated group O serum to obtain a concentration of 3000-3500 leukocytes/c.mm. A panel of donor leukocytes should be used, consisting of at least 2 or up to 12 different donor cells.
2. Sedimenting agent.
   - (a) 4% PVP solution in isotonic saline (warm solution to 37° C. to process). Adjust to pH 7.2 with 0.1N NaOH.

Procedure:

1. To 0.1 ml. inactivated unknown serum, add 0.05 ml. leukocyte suspension.
2. Incubate for 1 hr. in a water bath at 37° C.
3. Lyse red cells in the mixture by adding 0.1 ml. 2% acetic acid, mix gently, and allow to stand for 15 min.
4. Examine microscopically (×100) a drop of settled leukocytes from the bottom of the test tube for agglutination.

Treatment of agranulocytosis

Prior to 1942 the chief aim of physicians in treatment of agranulocytosis was to stimulate leukopoiesis by various agents—pentose nucleotide, yellow bone marrow, liver extract, and blood transfusions. These remedies usually proved inadequate, and the mortality rate in agranulocytosis remained high.

In 1942 Dameshek and Wolfson[668] introduced a new policy, i.e., not to worry about the bone marrow but to prevent or control the secondary infection; if infection and toxemia can be controlled, the bone marrow may take care of itself and recover spontaneously. Thus has developed the rationale for the use of sulfonamides and penicillin. Seven cases of agranulocytosis were successfully treated by sulfonamides, but because sulfonamides themselves may induce agranulocytosis, medical authorities turned to penicillin as an equally effective and safe remedy. It was found that penicillin could be used without harm in the presence of granulocytopenia or even of agranulocytosis resulting from severe infections.

In recent years, broad-spectrum antibiotics (tetracycline plus streptomycin, etc.), adrenal corticoids, and ACTH have been added to the physician's armamentarium. If the agranulocytosis is symptomatic in type, the primary disease should also be treated.

INFECTIOUS MONONUCLEOSIS

Historical review

Infectious mononucleosis, which has often been confused with acute lymphocytic leukemia, was first reported in the literature by Filatow[669] in 1885. Later, in 1889, Pfeiffer[670] described it again, calling attention to an infectious process characterized by very definite symptoms to which he gave the name glandular fever. West[671] reported an epidemic of 96 cases limited to children, with no evidence of throat infection. Tidy and Morley[672] reported more cases and described the disease again. They noted the enlargement of the axillary and inguinal glands but not the abdominal signs. Tidy[673] described the epidemic nature of infectious mononucleosis with an incubation period of from 5 to 15 days. Contact infection occurs only in the early stages of the disease, and direct contact or throat droplet infection is probably the mode of transmission. Sprunt and Evans[674] reported cases of this same disease occurring in young adults with infection of the upper respiratory tract with systemic reaction always present, together with the general glandular enlargement with frequent enlargement of the spleen. All cases showed lymphocytosis and moderate increase in the total number of white blood cells, together with a blood picture very much like that found in acute leukemia. There was no hemorrhage or severe anemia in any case reported. Longcope[675] reported cases with acute throat infection but no leukocytosis and very moderate increase in lymphoid cells. Downey and McKinlay[676] reported 9 cases with a study of the hematologic findings. Since 1923 a number of cases have been reported in the literature, together with 2 contributions, one by Bunnell[677] and one by Paul and Bunnell,[678] in which is pointed out a definite laboratory test, known as the **heterophil antibody test,** which will be described later.

Etiology

So far as etiology is concerned, a number of alleged causative organisms have been reported, notably *Listeria monocytogenes,* isolated from rabbits by Murray,[679] and from an apparent case in man by Nyfeld.[680] Other organisms have been described but have not been definitely established. Many believe this to be a viral disease, but all attempts to cultivate a virus have failed so far. It has been suggested that the virus, similar to the cold virus, must require very special growth conditions in vitro.[681]

Laboratory diagnosis

Lymph node biopsy

Examination of the biopsy material from lymph nodes of patients with infectious mononucleosis shows that the hyperplasia of lymphocytes is not as extensive as in cases of lymphadenosis. The atypical structure of the lymphomata and the increase in their number indicate that the disease is due to infection with some organism or virus which has a very specific stimulating effect on the lymphocytes and reticulum and a depressing effect on the granulocytic system.

Blood picture

There is no particular change in the number of red cells, the amount of hemoglobin, or the number of blood platelets in infectious mononucleosis. Leukopenia is striking in the beginning. There is usually leukocytosis coincident with enlargement of the lymphatic glands. The differential count shows a high lymphocyte count, often reaching a very high level, with the appearance of immature forms (Fig. 446). Downey and McKinlay[676] made an exhaustive hematologic study. They divided their patients into 3 groups, entirely dependent upon the type of atypical lymphocytes present in the blood picture.

Type I: The nucleus is oval, slightly lobulated, and contains a coarse mature chromatin. The cytoplasm is pale to dark blue, vacuolated (toxic), and abundant. Azurophilic granulation is often absent, but it may be prominent.

Type II: The cells are larger; the nucleus is round or oval and shows a mature chromatin pattern. The cytoplasm is large and pale and does not appear to be spongy. Other cells in this category have a somewhat plasma cell-like appearance due to a somewhat hyperchromatic eccentrically situated nucleus.

Type III: In this group are cells which are more immature, with deeply basophilic cytoplasm. Azurophilic cytoplasmic granules have been described in some of these cells. The nucleus is adult in type and round or oval.

These atypical cells appear in the peripheral blood from the fourth to fourteenth day, but their division into types serves no clinical purpose. Similar cells, virocytes, can be found in many viral diseases, such as hepatitis, upper respiratory viral infections, measles, viral pneumonia, herpes zoster, and herpes simplex. There is also some evidence that these cells do not represent a specific response to viral stimuli since they can also be seen whenever allergic and hormonal stimuli produce lymphocytic changes.[682] Recent electron microscopic studies of the leukocytes in infectious mononucleosis have failed to shed light on the nature of these cells.

The peroxidase test on these cells is negative, which would incline one to believe in their lymphocytic origin. Osgood[683] directed particular attention to the nuclear fenestrations in the mature small lymyphocytes of this disease. These fenestrations are multiple holes and are considered by Osgood of definite diagnostic importance. The hemograms shown

in Table 265 from a case of infectious mononucleosis illustrate the hematology of the disease.

Serology

Heterophil antibody test

Because of the difficulty in making an absolute diagnosis on clinical and cytologic grounds, the suggestion of a serologic diagnostic test, proposed by Paul and Bunnell[678] in 1932, was hailed with a great deal of satisfaction. This test is based on the presence of sheep heterophil antibodies in the blood of the patient. The heterophil antibody concerned may be defined as an antibody reacting with an agent other than and phylogenetically unrelated to the specific antigen responsible for the production of the antibody in question. The presence of increased sheep heterophil antibodies in the blood in patients with infectious mononucleosis was rapidly confirmed by a number of independent investigators.

Presumptive test

The following technic for the heterophil antibody test is adapted by Kracke[684] from Davidsohn, Bernstein, Paul, and Bunnell.

Procedure: Eleven tubes are required for the test —10 for the serial dilutions of the patient's serum and the eleventh for a control over saline and sheep cells used.

1. To tubes 2, 3, 4, 5, 6, 7, 8, 9, 10, and 11 add 0.5 ml. physiologic saline. Tube 1 receives no saline.
2. Pipet 0.5 ml. patient's inactivated serum (heated to 55°-56° C. for 15 min.) into tube 1. The serum is heated to inactivate complement to prevent the action of possible anti-sheep cell hemolysins.
3. Place 0.5 ml. of patient's inactivated serum in tube 2.
4. Mix the contents of tube 2 carefully by drawing in and out of the pipet, and transfer 0.5 ml. to tube 3.
5. Mix the contents of tube 3 in the same manner and pipet 0.5 ml. into tube 4; then continue in this manner through tube 10.
6. Mix the contents of tube 10 and discard 0.5 ml. Tube 11 receives no serum.
7. Dilutions of serum in the 10 tubes are now as follows: (1) undiluted, (2) 1:2, (3) 1:4, (4) 1:8, (5) 1:16, (6) 1:32, (7) 1:64, (8) 1:128, (9) 1:256, and (10) 1:512.
8. To each of the 11 tubes add 0.5 ml. 2% suspension of sheep cells. The sheep cells are prepared in physiologic saline. Wash 3 times immediately before use by adding 3 times their vol. physiologic saline and centrifuging until firmly packed, removing the supernatant fluid each time before adding fresh saline. After the last centrifuging remove the saline and make a 2% suspension by adding 49 vol. saline to the packed sheep cells.
9. After the addition of the sheep cell suspension, add 1 ml. saline to each of the 11 tubes. The total quantity in each tube is now 2 ml.
10. Shake the tubes thoroughly and let stand at room temperature for 2 hr. Initial reading may be made after 15 min.

Report the highest dilution which shows macroscopic agglutination after gently shaking the tubes to resuspend sediment. The titer is the reciprocal value of the highest serum dilution showing agglutination.

There are many factors that limit the usefulness of this test. Forssman in 1911 described a nonspecific antigen which is present in the tissues of various animals, such as the guinea pig, horse, rabbit, and pig, but is absent in man, sheep, etc. If horse serum, for instance, is injected into patients, antibodies acting on sheep erythrocytes will appear. Such so-called heterophil antibodies are present in normal persons and may reach a titer of 1:64. This titer may rise in viral infections, allergies, and certain blood diseases such as polycythemia, acquired hemolytic anemia, myelogenous leukemia, etc. The heterophil antibody test is therefore nonspecific and is usually referred to as a **presumptive test.** It is considered to be positive if agglutination occurs in a dilution of 1:64.

Sheep heterophil antibodies similar in character to those found in infectious mononucleosis had been previously demonstrated by Davidsohn[685] and many others in the blood of individuals after injections of native or therapeutic horse serum, particularly when serum sickness developed. Davidsohn[686] has also shown that such antibodies might persist in the blood of a patient for a year or more after treatment with horse serum.

Differential absorption test

Stuart et al.[687] found that the sheep antibodies in serum sickness were completely adsorbed by emulsions of guinea pig kidney, whereas those of infectious mononucleosis were not, proving that the heterophil antibody in infectious mononucleosis is not a pure anti-Forssman-antigen-antibody, as the latter is completely adsorbed by any Forssman antigen such as guinea pig kidney. On the other hand, the heterophil antibody in infectious mononucleosis is completely adsorbed by beef erythrocytes.

The patient's serum should be titrated for antisheep agglutinin in 3 ways: (1) unadsorbed, (2) after adsorption with guinea pig tissue, and (3) after adsorption with beef tissue.

Equipment:

1. 24 test tubes, 75 × 12 mm.
2. 1 test tube rack.
3. 4 pipets, 0.25 ml.
4. 2 pipets, 0.50 ml.
5. 2 pipets, 1 ml., graduated in 0.1 ml.
6. 2 sterile syringes, 1 and 2 ml.
7. 2 sterile needles, 20 gauge.
8. 2 dropper pipets.
9. 2 centrifuge tubes, 15 ml., graduated.
10. 1 water bath regulated at 56° C.
11. 1 centrifuge.
12. 1 clock or watch.
13. 1 viewing box such as is used for blood grouping tests.

Reagents:

1. Sodium chloride solution, 0.85%.
2. Patient's serum.
   (a) Obtain in the usual manner and inactivate in a water bath at 56° C. for 30 min.
3. Sheep red blood cells, 2%.
   (a) Make either from freshly secured blood or prepare from preserved sheep cells.
   (b) Place 1.5 ml. well-mixed suspension of sheep cells into a 15 ml. centrifuge tube.
   (c) Wash 3 times in saline or until the supernatant saline is clear and colorless. This should leave about 0.3 ml. packed sheep cells. Dilute 0.3 ml. sheep cells with saline to 15 ml. to make a 2% suspension.
3. Guinea pig kidney antigen. This can be obtained ready for use.*
4. Beef cell antigen. This can be obtained ready for use.*

Procedure:

Titration of unadsorbed serum:

1. Place 6 test tubes in a test tube rack.
2. Place 0.4 ml. saline in the first tube.
3. Place 0.25 ml. saline in each of the other tubes.
4. Add 0.1 ml. patient's inactivated serum to the first tube.
5. Mix by drawing into and out of a pipet several times.
6. Transfer 0.25 ml. from the first to the second tube, and mix. Transfer 0.25 ml. to the next tube and mix.
7. Continue transferring and mixing through tube 6. This leaves 0.5 ml. in tube 6. Remove and discard 0.25 ml. from tube 6.
8. Add 0.1 ml. of washed sheep cell suspension to each tube.
9. Shake well and let stand at room temperature for 2 hr.
10. Examine for clumping of the red blood cells after gently shaking the tubes.

According to Davidsohn (adapted from Stuart and co-workers), the final dilutions are 1:7, 1:14, 1:28, 1:56, 1:112, etc. (This apparently includes the quantity of sheep cells used: first tube contains 0.05 ml. serum in a total of 0.35 ml.)

The titer is the weakest dilution of the serum which gives clumping that is visible to the naked eye.

Titration of serum adsorbed by guinea pig antigen:

1. Shake the suspension of guinea pig antigen thoroughly and place 1 ml. in a test tube.
2. Add 0.2 ml. inactivated serum.
3. Shake the tube well and centrifuge at high speed for 5 min.
4. Transfer the supernatant liquid with a capillary pipet to a clean test tube. This is the adsorbed serum.
5. Place 0.25 ml. saline in each of 6 tubes.
6. Add 0.25 ml. adsorbed serum to tube 1.
7. Mix and transfer serially 0.25 ml. to each tube; discard the last 0.25 ml. from tube 6.
8. Add 0.1 ml. washed sheep cells to each tube.
9. Shake well and let stand at room temperature for 2 hr.
10. Examine for clumping of the red cells after gently agitating the tubes.

The final dilutions are 1:14, 1:28, 1:56, etc. (includes the added sheep cells).

The titer is the weakest dilution of serum which gives clumping visible to the naked eye.

Titration of serum adsorbed by beef cell antigen: Proceed exactly as for guinea pig antigen, using thoroughly shaken beef blood cell antigen in place of the guinea pig antigen.

Interpretation of results

Beef cell antigen adsorbs the infectious mononucleosis (I.M.) antibody completely, whereas guinea pig antigen does not. For example, if the titer with unadsorbed serum is 1:56, and the patient has infectious mononucleosis, the titer after beef cell adsorption will be 0 or nearly 0, whereas after guinea pig adsorption it will be 1:56, 1:28, or even 1:14, but no lower.

The titer of the presumptive test is less important than the adsorption results.

It must be remembered that the specific infectious mononucleosis antibodies are not pres-

---

*An excellent preparation of guinea pig kidney antigen and beef red cell antigen is available from Certified Blood Donor Service, Jamaica, L. I., N. Y.

Table 266. *Differential adsorption of heterophil antibodies*

ent throughout the disease, and they should be sought on more than one occasion if the clinical symptoms and the blood findings are suggestive of infectious mononucleosis.

Very recently (1961) Tomcsik[688] described a new serologic test for the diagnosis of infectious mononucleosis using trypsinized beef erythrocytes and only 5 test tubes. This test appears to be as specific as the Davidsohn test but is much shorter and less complicated.

ACUTE INFECTIOUS LYMPHOCYTOSIS

Carl H. Smith reported[689] an account of a new disease entity, acute infectious lymphocytosis. He reported 2 cases in 1941 and saw 4 cases during March, 1943. The fact that 3 of the patients were members of one family and 1 a hospital contact impressed him with the possible communicability or infectiousness of the disease. Other cases have been reported at various hospitals in New York City where these first cases were noted.

This is a disease with an elevated leukocyte count persisting for approximately 3-5 wk. The clinical course varies in intensity. The disease has a possible incubation period of 12-21 days and may be marked by varying degrees of constitutional reaction at the onset, such as vomiting, irritability, and fever, together with acute abdominal signs and symptoms and occasionally signs of involvement of the nervous system. There is no lymphadenopathy nor is there a palpable spleen. The heterophil agglutination reaction is uniformly negative. In 2 of the cases the biopsy of a lymph node showed strikingly similar microscopic appearance. An oustanding feature in these biopsies was a striking proliferation of the reticuloendothelium of the sinuses, which were blocked by masses of cells. In addition, the lymph follicles showed a number of changes. Some of the germinal centers showed a hyaline degeneration of varying degree. Many of the follicles were notably inconspicuous, and in some sections they were practically obliterated. A feature common to most of the cases was infection of the upper respiratory tract.

The striking feature of these cases was the hyperleukocytosis with relative and absolute lymphocytosis persisting for a prolonged period. Normal small lymphocytes accounted for this increase and presented the most important diagnostic element of the blood picture.

The differential diagnosis from leukemia was based largely on the absence of lymphoblasts. Lymphoblasts are usually round, large, and uniform in size and show a distinct nuclear pattern. Besides, in acute lymphocytic leukemia with a hyperleukocytosis of the magnitude found in infectious lymphocytosis the blood would show a severe anemia and a decrease in platelets, and enlargement of the spleen and lymph nodes would be noticed.

Examination of the bone marrow also serves to differentiate between leukemia and this disease. In acute lymphocytic leukemia in children, marrow aspiration shows complete replacement of the bone marrow by lymphoblasts. In acute infectious lymphocytosis, on the other hand, the myeloid and erythroblastic elements are present in normal proportions and the only abnormality is the presence of normal lymphocytes in increased percentage.

In the first case the first blood count showed 45,000 white cells/c.mm., 45% neutrophils, and 48% lymphocytes. In a few hours, the white cell count rose to 55,400 with 72% lymphocytes. The total count in some cases ran as high as 68,300, and the lymphocytosis amounted to as much as 90% in one case. The elevated blood levels persist from 3-5 wk.

The normal lymphocytes in this disease are in sharp contrast to the atypical and abnormal lymphocytic elements in infectious mononucleosis and to the lymphoblasts in leukemia.

The heterophil agglutination reaction was uniformly negative in these cases, and the serologic reactions were negative for lymphocytic choriomeningitis and for influenza A and B virus.

In all cases the disease was uncomplicated and had a uniformly favorable outcome.

LUPUS ERYTHEMATOSUS (L.E.) CELL PHENOMENON[690]

The discussion of the lupus erythematosus factor (L.E.) follows the discussion of agranulocytosis because during the last decade the causative factor has been identified as an autoantibody.

The often bizarre clinical patterns observed in disseminated lupus erythematosus have made the diagnosis of this disease difficult, especially when the typical skin manifestations are absent. A diagnostic aid was added with the finding of the L.E. cell in bone marrow by Hargraves et al.[690] These bone marrow findings were soon verified,[691, 692] and others[693, 694] were able to find these cells in the peripheral blood of patients with lupus erythematosus. Since the original description of this unusual cell, it has been shown that the serum (or plasma) of patients with lupus erythematosus will reproduce the phenomenon when added to the bone marrow[693, 695] or the blood[696, 697] of normal persons or of patients suffering from diseases other than lupus.

These observations led to the conclusion that the abnormal factor was present in plasma, and Haserick[698] identified its association with the gamma globulin fraction. Kurnick et al.[699-701] have reported that in addition to the specific factor present in fraction II of L.E. sera, other elements participate in the phenomenon, namely (1) deoxyribonuclease, (2) an inhibitor of deoxyribonuclease, and (3) a factor or factors in fraction III of normal and L.E. sera. Kurnick et al.[702] have followed these ideas with determination of the susceptibility of leukocytes from different animal species to alteration by lupus erythematosus serum. These observers found that the leukocytes of the chicken and horse were the most susceptible and that those of the guinea pig and dog were highly susceptible. In all these species, the demonstration of L.E. cell formation was much more striking than when using human leukocytes, and they recommend an animal substrate of leukocytes for performing the L.E. cell test.

Very early in the observations on the L.E. phenomenon it was realized that the abnormal cells were not dependent on anticoagulant, and it was possible to demonstrate L.E. cells in sections.[703, 704]

Table 267. *Means of differentiating some conditions characterized by lymphocytosis*

	Pertussis	*Aleukemic leukemia*	*Chronic lymphocytic leukemia*	*Acute lymphocytic leukemia*	*Acute infectious lymphocytosis*
White cell count	May be 40,000 or higher	Normal or subnormal	Very high; 50,000 and up	Extremely high; up to 1,000,000	Very high; 45,000-70,000
Red cell count	No significant change	Low	Low	Very low	Usually normal
Hemoglobin	No significant change	Low	Low	Very low	No significant change
Number lymphocytes characteristically present	60-80%	About 60%	As many as 90-100%	Up to 100%	45-90%
Size of lymphocytes	Small	Large	Small	Large	Mostly small
Pathologic or special forms of lymphocytes	—	Lymphoblasts; Rieder forms; atypical lymphocytes; plasma cells	Lymphoblasts sometimes found; plasma cells	Lymphoblasts: many atypical; plasma cells	None
Pathologic red cells	—	Normoblasts; polychromasia; other nucleated reds may be seen	Normoblasts; polychromasia	Normoblasts and other nucleated reds; pathologic forms; polychromasia, etc.	None
Blood platelets	No significant change	Low	Low	Low or absent	Normal
Bone marrow	—	Lymphatic	Lymphatic	Lymphatic	Normal except for lymphocytosis

The finding of L.E. cells in the peripheral blood or bone marrow of any patient imposes a diagnosis of lupus erythematosus although a few exceptions to this statement are to be found: individual cases of dermatitis herpetiformis,[705] pernicious anemia,[705] leukemia,[706] multiple myeloma,[707] and primary amyloidosis.[704] Haserick[708] contaminated plasma samples with fungi and simulated the L.E. cell phenomenon. Walsh and Zimmerman[709] have reported 3 cases of severe penicillin reaction in which L.E. cells were found in the bone marrow and the plasma factors in the plasma. A lupuslike syndrome has been described in patients treated with hydralazine (Apresoline) for hypertension,[710] in which L.E. cells can be demonstrated. The phenomenon disappears after withdrawal of the drug. Despite these few exceptions, the finding of L.E. cells should be strong evidence of the diagnosis of lupus erythematosus unless proved otherwise. On the contrary, failure to demonstrate such cells does not militate against such a diagnosis.

L.E. cells are most abundantly present in the acute cases of lupus erythematosus and are particularly easy to demonstrate in the terminal phases of the disease. The finding of L.E. cells in patients in remission is variable. At times there are inexplicable variations in numbers of L.E. cells. Occasional patients are seen whose preparations contain numerous L.E. cells on one day and only rare forms the following day.

As with many other laboratory searches, the incidence of positive L.E. preparations is proportional to the vigor with which the pursuit is made, and often many preparations must be made on a given patient before these cells are found.

The positive L.E. test exhibits 3 phenomena: (1) the L.E. cell, (2) rosettes, and (3) the so-called free Klemperer (hematoxylin) or nuclear bodies. The last 2 phenomena are helpful in the diagnosis of L.E., but only the first is diagnostic. L.E. cells are usually neutrophils which contain within their cytoplasm

Infectious mononucleosis	*Agranulocytosis*	*Idiopathic aplastic anemia*	*Pernicious anemia*	*Endocrine disturbance*	*Chronic tuberculosis*
Normal or slight leukocytosis	Very low, below 2500; may be below 1000	Progressively lowered; may be below 500	Low; average around 3000; may be lower	High normal	High normal
No significant change	Normal or slightly lowered	Progressively lowered; may be below 1,000,000	Low, around 1,500,000-3,000,000	No significant change; usually lowered	No significant change
No significant change	Lowered	Progressively lowered	Low	Often lowered	No significant change
Around 60-70%	May be as high as 90-100%	May be normal or up to 100%	Around 40-50% or higher	About 40-45%	40-50%
Large	Small	Very small	Large	Large	Large; size depends upon amount healing
Types I, II, and III special forms seen in this disease; plasma cells	—	—	—	—	—
None	None	None; as a rule not even polychromasia	Megaloblasts and megalocytes; macrocytic hyperchromic erythrocytes; polychromasia, etc.	Polychromasia; sometimes basophilic punctation; occasional normoblasts	No significant change

	Aplastic type or packed bone marrow	Fatty degeneration or infiltration with small lymphocytes	Megaloblastic	—	Left shift

large homogeneous, amorphous, violaceous inclusions. If the inclusions are atypical and more or less retain the nuclear chromatin pattern, we call these cells **tart cells** after a patient named Tart in whose blood Hargraves found these cells. They are pseudo-L.E. cells, are not diagnostic of L.E., and represent phagocytosis of hypersensitivity. Rosettes are clusters of neutrophils surrounding amorphous nuclear material. The free Klemperer bodies are free amorphous nuclear material.

The formation of the L.E. cell occurs in 2 phases. The first step is the action of a plasma factor (L.E. factor) on white cell nuclei which lose their chromatin pattern and are released from the disintegrating cell. In the second step, these freed and altered nuclei are phagocytosed by uninjured white cells. The L.E. factor is able to act on the nuclei of any of the white cells in the peripheral blood or bone marrow. The phagocytosing cells comprise mainly polymorphonuclear neutrophilic cells but occasionally also eosinophils, basophils, and monocytes.

The L.E. factor is a gamma globulin. Its activity can be neutralized by antihuman gamma globulin serum. It is present not only in the plasma of L.E. patients but also in other protein-containing fluids, such as exudates, transudates, and protein-containing urine. The L.E. factor crosses the placenta and produces a transitory L.E. cell phenomenon in newborn babies of affected mothers. Goodman[711] showed that under the influence of the L.E. factor the nucleus imbibes water and protein so that it swells. The imbibed protein replaces histon in the nuclear deoxyribonucleic acid, producing the characteristic homogeneous amorphous staining quality of the affected nucleus.

What is the L.E. factor? Based on the action of antileukocytic antibodies (leukoopsonins) and their production of nucleophagocytosis, it has been suggested that an immune serum is responsible for the L.E. phenomenon.

With the help of immune electrophoretic technics and the single and double diffusion technics of Oudin and Ochterlony, it has been established that the L.E. factor is an antinuclear antibody produced in response to nucleoprotein.[712, 713, 715] This may not be the entire story. Bensze has repeatedly shown evidence of the existence of transferable and nontransferable L.E. plasma factors. The antinuclear L.E. factor fulfills most of the criteria of antibody except that of specificity since it attacks cells of widely separated species. It also overlaps with antibodies found in other diseases, such as rheumatoid arthritis, Hashimoto's disease, and hepatitis.

Laboratory diagnosis of lupus erythematosus

Hematologic findings

Red blood cells: There is usually a normocytic normochromic anemia which may be due to hemolysis or to bone marrow depression. If the anemia is hemolytic, the Coombs test is frequently positive.

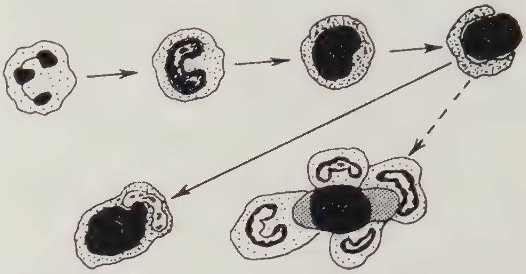

Fig. 437. Outline of nuclear lysis and formation of L.E. cell and rosette. (Modified from Robineaux, R.: Étude microcinématographique en contraste de phase du mécanisme du phénomène LE. In Grabar and Miescher, editors: Immunopathologie, Symposium, Basel, 1958, Benno Schwabe & Co.)

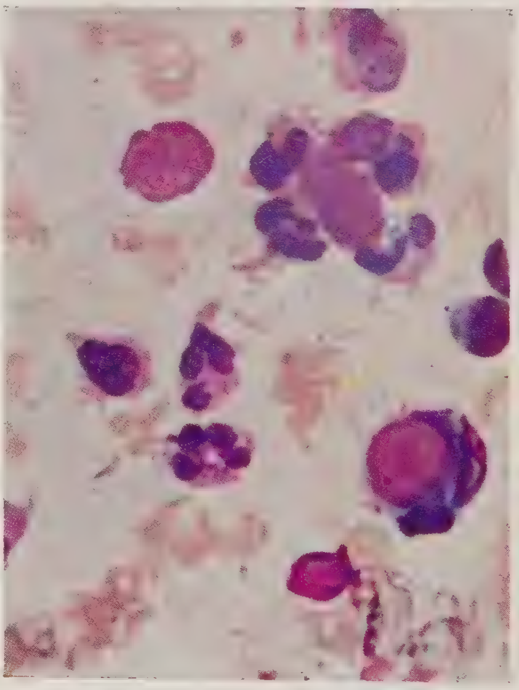

Fig. 438. Lupus erythematosus (L.E.) cells. Cluster in upper right-hand corner is a typical rosette with an L.E. body in the center. The cell containing a body in lower right-hand corner is a tart cell, which is not pathognomonic of lupus erythematosus. Source of material, bone marrow. (×800.)

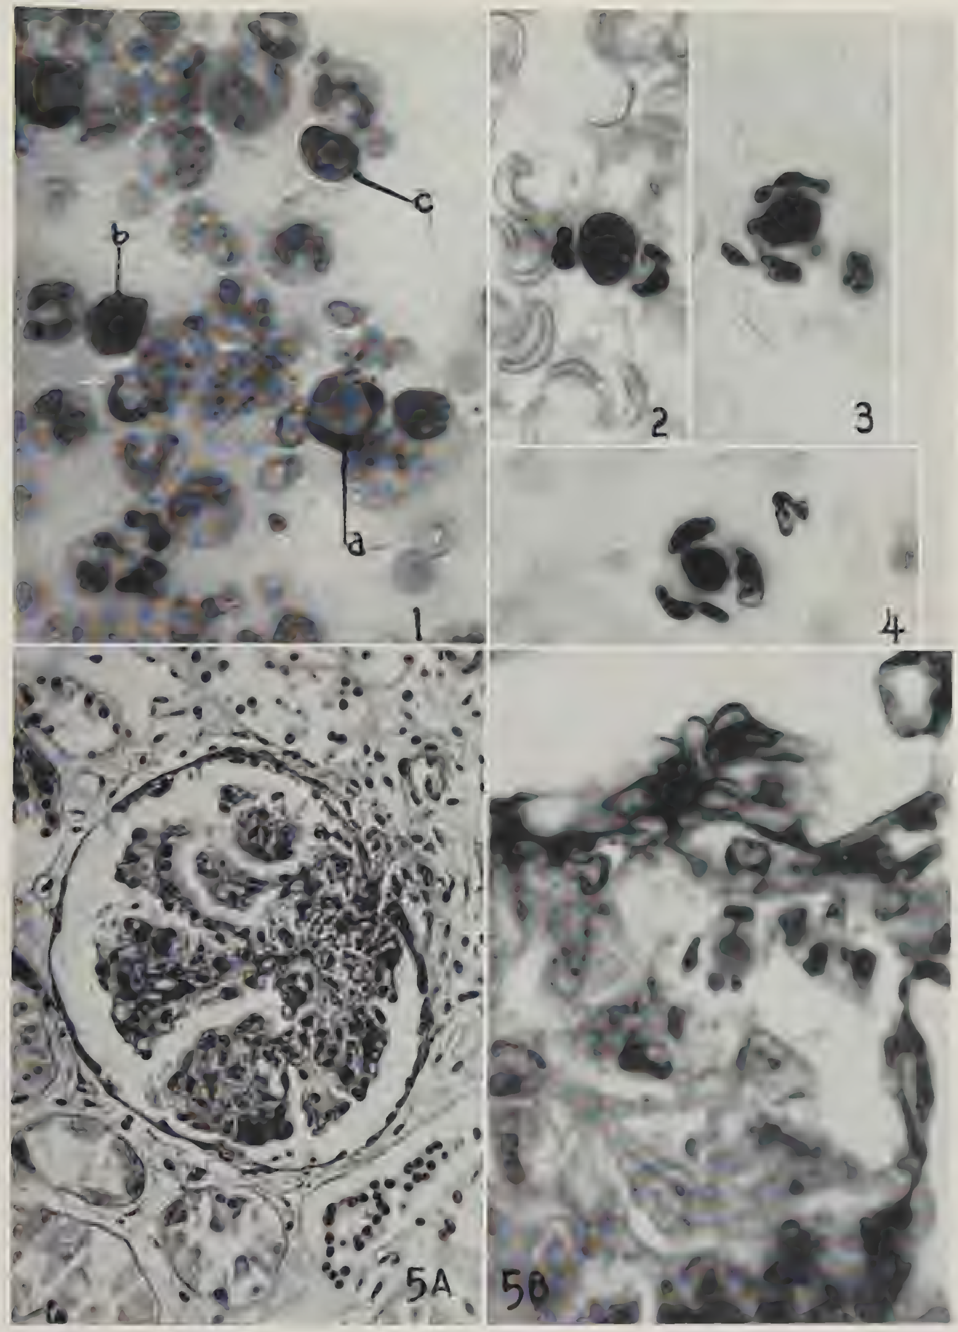

Fig. 439. Lupus erythematosus (L.E.) cell phenomenon. Bone marrow spreads and tissue sections. **1,** Spread of sternal marrow aspirate. An intracellular, **a,** and an extracellular, **b,** L.E. body are seen in addition to a degenerated nucleus, **c.** (Wright-Giemsa stain; ×940.) **2,** Paraffin section of the sternal marrow aspirate with an L.E. cell. (H & E stain; ×1530.) **3,** Paraffin section of the sternal marrow aspirate with an L.E. cell. Tissue has been treated with ribonuclease and stained with toluidine blue. L.E. body stains similarly to the nuclear material. (×1530.) **4,** Paraffin section as in **3.** Tissue has been stained by the Fuelgen method; L.E. body stains similarly to the nuclear material. (×1530.) **5A,** Paraffin section of kidney of a patient with clinical and autopsy diagnoses of disseminated lupus erythematosus. Sections have been treated with hyaluronidase and stained by the Hotchkiss method. Intracellular and extracellular L.E. bodies were seen. (×280.) **5B,** Higher power of **5A,** showing a typical L.E. cell. (×1530.) (From the collection of H. Agress.)

White blood cells: There is usually leukopenia unless infection is responsible for the leukocytosis. Eosinophilia is rarely seen.

Platelets: Thrombocytopenia is frequent and is responsible for hemorrhagic manifestations such as purpura. In any patient who appears to have idiopathic thrombocytopenic purpura, lupus erythematosus should be excluded.

Methods for demonstrating L.E. cell

Clot method

1. Withdraw 7 ml. venous blood, allow to clot and discard serum.
2. With a pestle grind the clot through a fine wire mesh screen.
3. Discard the fibrin left on the screen and collect the sieved portion.
4. Distribute the latter in Wintrobe sedimentation tubes and centrifuge at 1000 r.p.m. for 10 min.
5. Make smears of the buffy coat only and stain with Wright stain.
6. Examine for L.E. cells with high dry magnification.

Rapid slide screening test

This test employs a reagent prepared from polystyrene latex and deoxyribonucleic protein.* The test is new (1961). It is hoped that it will solve the frequent difficulty of distinguishing rheumatoid arthritis from L.E. Rothfield et al.[716] in a recent series consider this test superior to the L.E. test.

Our own experience and that of Dubois[717] differ from Rothfield's inasmuch as, although we admit that the test is specific, we do not consider it sensitive enough to be used as a screening procedure.

Other tests for L.E. cells

Mudrick and others[718] described a capillary L.E. cell test which does not require special equipment but can be done in microhematocrit tubes and has the advantage of incubation of the plasma L.E. factor with mainly leukocytes.

Rebuck et al.[719, 720] showed that a patient who has L.E. may form L.E. cells in his own skin window either spontaneously or after addition of his (patient's) own plasma to the skin window.

Nonhematologic findings

Plasma proteins: There is an increase in the globulin fraction (hypergammaglobulinemia) with or without depression of albumin, depending somewhat on the state of the kidneys. The increase in fibrinogen and in gamma globulin is responsible for the increased sedimentation rate in L.E. These protein changes may also be responsible for positive flocculation tests even without liver disease, for the high heterophil antibody titer, and for the falsely positive serologic tests for syphilis.

Urine: Proteinuria is found if the kidneys are involved.

Synovial and pleural fluids: These fluids may contain L.E. cells.

L.E. is a protean disease which may affect almost any body system, but the present discussion is confined to those manifestations which can be detected in the laboratory.

SUMMARY OF LEUKOCYTIC CHANGES IN VARIOUS PATHOLOGIC CONDITIONS

The following summary offers a recapitulation of the changes in the Schilling differential count seen in various pathologic conditions.

Leukocytosis with increase in basophils:

1. Myelocytic leukemia.
2. Polycythemia vera.
3. Serum injection.
4. Hemophilia.
5. Convalescence from beriberi.
6. After multiple blood transfusions.
7. In many conditions customarily accompanied by eosinophilia.

Eosinophilia with increased white cell count:

Note: It is a biologic rule that severe irritations do not cause weaker or paradoxical reactions; i.e., the same processes which in moderate degrees may produce eosinophilia in greater degrees cause either hypereosinophilia or aneosinophilia.

1. Exudative processes: bronchial asthma, exudative diathesis and exudative intestinal catarrh of children, colitis membranacea, Quincke's edema, etc.
2. Anaphylaxis and anaphylactoid conditions: serum disease, hay fever, urticaria, migraine, idiosyncrasies, etc., and irritations of the vagus nerve.
3. All diseases due to worms wherever located (eosinophilia may dwindle to aneosinophilia [insufficiency] because of overinfestation): trichinosis, schistosomiasis hepatica, ancylostomiasis, bilharziasis, filariasis, *Diphyllobothrium latum* infestation, echinococcosis, and intermittently with all intestinal parasites.
4. Skin diseases: psoriasis, pemphigus, urticaria, eczema, herpes zoster, impetigo contagiosa, some dermatitides, prurigo hebrae, premykotic exanthema, mycosis fungoides, purpura.
5. Scarlet fever beginning on the third day of the eruption.
6. Gonorrhea, especially in females.
7. Tumors occasionally, especially those of the lungs and peritoneum; rectal carcinoma, especially in serous metastases.
8. Nephrosis or nephritis occasionally (slight affections).

---

*Hyland Laboratories, Los Angeles, Calif.

9. Muscular rheumatism (Bittorf).
10. Leukemia. This serves to differentiate leukemia from leukemoid pictures.
11. Pernicious anemia in the beginning, during remissions, and under liver therapy.
12. Convalescence from infections (good sign).

Decrease or absence of eosinophils (considered an unfavorable symptom):

1. Overirritation of eosinophilic processes, particularly in severe affections.
   (a) Due to worms.
   (b) Height of serum disease.
   (c) Pernicious anemia in severe stages.

Normal total neutrophils and low white blood cell count:

1. Severe pernicious anemia (this usually shows neutropenia).
2. Severe aplastic anemia (this usually shows neutropenia).
3. Osteoscleroses and diseases with reduction of bone marrow.

Neutrophilia without shift but with increased white blood cell count:

1. During digestion.
2. Muscular activity.
3. Spasmodic conditions.
4. After hemorrhages.
5. Polycythemia (at times a slight shift).
6. Very superficial or benign infections.
7. Simple intestinal catarrh.
8. Nephritides.
9. Abortive cases of infectious disease.
10. Polyarthritis acuta (often shows a right shift, an acute infection without a left shift).
11. Tetanus.
12. Struma.
13. Uncomplicated malignant tumors.
14. After sodium chloride infusions temporarily.
15. After certain medicaments.
16. During violent internal or external hemorrhages.

Neutrophilia with slight stab shift with high normal or increased white blood cell count:

1. Mild cases of acute infections and protozoal diseases: anginas, catarrhs, and malaria during attacks.
2. Severe diseases of the digestive system: intestinal catarrhs and liver diseases including jaundice in which the epithelia are alone involved.
3. Superficial, benign, or encapsulated infections.
   (a) After operations.
   (b) After incision of abscesses.
   (c) Suppurative wounds without general involvement.
   (d) Slight catarrhal appendicitis.
   (e) Open suppurations of eyes, ears, and pharynx.
   (f) Appendicitis, gynecologic, and liver pus collections, entirely encapsulated.
   (g) Chronic diseases with neutrophilic irritation (septicemias and endocarditis).
   (h) Broken-down ulcerative tumors.
   (i) Mild active tuberculosis.
   (j) Tuberculous abscess formation.

These slight shifts are important for the following reasons:

1. To determine infectious processes.
2. To estimate the latent continuance of apparently healed infections or the danger of relapse.
3. To outline as relatively harmless acute illnesses or exacerbations of severe conditions which have been reactivated.

Neutrophilia with regenerative shift and increased white blood cell count:

1. Very violent exercise (marathon races).
2. Diabetic coma.
3. Pregnancy.
4. Severe cases of many acute infectious diseases: pneumonia, senile pneumonia, diphtheria, scarlet fever, cholera, bacterial dysentery, erysipelas, meningitis epidemica, typhus, and variola.
5. Acute protozoal disease during attacks.
6. All acute and progressive internal infections: beginning empyema, newly formed abscess, appendicitis destructiva et perforata, peritonitis, purulent inflammation of bile ducts and urinary passages, pus infection of bone marrow, encapsulated malignant pustular affections of ears, eyes, and pharyngeal region, fresh cerebral suppurations, gynecologic processes, eclampsia, puerperal fever, severe intoxications due to bacterial poisons, heavy metals (lead, sublimate, and etc.), coal gas, Lysol, phenylhydrazine.
7. Subsequent effects of leukopenic infection.
8. Acute exacerbations of chronic infections: tuberculosis and endocarditis.
9. Transition of leukopenic infection into one with severe regenerative complication: influenza with pneumonia.

Neutrophilia with hyperregenerative shift with decreasing or low white blood cell count and absolute aneosinophilia (usually an agonal symptom of very serious significance):

1. Very severe infections.
2. Perforation peritonitis.
3. Lobar pneumonia.
4. Malaria comatosa.
5. Fatal blackwater fever.

Liberation leukocytosis (with involvement of erythrocytes):

1. Complicated bone fractures.
2. Metastases of tumors.
3. Lymphogranulomas.
4. After intravenous injections and transfusions with bad reaction.
5. Blood crises, particularly in pernicious anemia, hemolysis, and blackwater fever.
6. Nonleukemic myelosis (aleukemic myelosis).
7. Marble disease (Albers-Schönberg disease).
8. Simple myelogenous metaplasia of the spleen.

Persisting leukemoid leukocytosis:

1. Persisting direct irritation of bone marrow.
   (a) Carcinomatosis.
   (b) Malignant granuloses.
   (c) Polycythemia vera with hyperplasia of erythropoiesis.
2. Severe anemias complicated with infection.
3. Doubtful acute myelocytic leukemia.
4. Improved stages of agranulocytosis during cure (penicillin).

Neutrophilia with degenerative shift with high normal white blood cell count:

1. Mixed cases (typhoid with sepsis and tuberculosis with secondary infection).

2. Chronic or less virulent infections (hepatic abscess, recurrence, and endocarditis).

Neutropenia with low white blood cell count and marked stab shift:

1. Kala-azar.
2. Other protozoal diseases **after** attacks.
3. During uncomplicated typhoid and paratyphoid fever.
4. Parotitis epidemica in severe cases.
5. Pappataci fever.
6. Brucellosis (this sometimes shows neutrophilia).
7. Influenza.
8. Dengue.
9. Not infrequently in tuberculosis.

Neutropenia with low white blood cell count and no known shift:

1. Pellagra.
2. Yellow fever.
3. Spotted fever.
4. Kedani or tsutsugamushi (scrub typhus).
5. Chickenpox.
6. Poliomyelitis acuta.
7. Ophthalmia sympathica.
8. Pernicious anemia.

Neutropenia with low total white blood cell count and no shift and often total absence of neutrophils:

1. Agranulocytosis.
2. Aplastic anemia.
3. Experimentally in anaphylaxis.

Neutropenia with shift to the right:

Note: These pictures show absence or diminution of stab cells and numerous highly segmented neutrophils with 6 or more segments and dense granules and a tendency to large ovoid cells.

1. Pernicious anemia.
2. Very severe anemias with pernicious blood picture.
    (a) Syphilis.
    (b) Pernicious anemia of pregnancy.
    (c) Sprue.
    (d) Carcinoma of the stomach.
    (e) *Diphyllobothrium latum* infestation.
    (f) Less frequently in other worm diseases.
    (g) Occasionally in malaria and septic processes.
    (h) Less marked in avitaminoses (pellagra).
    (i) Conditions due to insufficient food.
    (j) Cirrhosis of the liver.

Lymphocytosis with increased total white cell count:

1. Constitutional in some individuals.
2. First phase of physiologic or very slight irritation leukocytosis during exercise, digestion, etc.
3. Epilepsy during the attacks.
4. Lymphocytosis of crying nursing infants.
5. Parotitis epidemica during course of mild cases.
6. Pertussis.
7. Uncomplicated benign (afebrile) tuberculosis and syphilitic processes.
8. After certain medicaments such as epinephrine.
9. Lymphocytic leukemia.
10. Acute infectious lymphocytosis.
11. Infectious mononucleosis.

Lymphocytosis with normal or low white blood cell count:

1. All conditions with neutropenia as an associated condition.
2. Lymphocytic aleukemia.
3. Granulomatoses, especially in stages without fever.
4. Neurasthenia and vagotonia (constitutional).
5. Basedow's disease.
6. Acromegaly.
7. Myxedema.
8. Aregenerative anemias, particularly pernicious anemia.
9. Most protozoal diseases during recurrence.
10. During attacks or intervals of conditions caused by viruses.
11. Beriberi.
12. Pure scurvy.
13. Metabolic diseases in chronic stages similar to conditions of hunger.
14. Achylia gastrica simplex.
15. Uncomplicated benign tuberculosis.
16. Uncomplicated syphilis.
17. Continued roentgen exposure.
18. After infections, as a phase of recovery.
19. After vaccinations (typhoid, cholera, dysentery, tuberculin, etc.)

Lymphocytosis with marked low total white blood cell count:

1. Influenza.
2. Pappataci fever.
3. Typhoid fever.
4. Brucellosis.
5. Kala-azar.
6. Agranulocytosis.
7. Aplastic anemia.
8. Pernicious anemia.

Lymphocytopenia with increased white blood cell count:

1. Relative in myelocytic leukemia.
2. Accompanying symptom in conditions with neutrophilia.
3. Severe infections.

Lymphocytopenia with normal, subnormal, or very low white blood cell count:

1. Marked in measles shortly before and after the outbreak of the exanthem.
2. Sometimes in yellow fever and typhus.
3. Malignant attacks of certain diseases with lymphocytic changes (typhoid fever).
4. Paroxysmal hemoglobinuria during attacks.

Monocytosis with increased white blood cell count:

1. In health or slight illnesses if the first drop of blood from the ear is used without cleaning and rubbing the ear.
2. Endocarditis ulcerosa (cells endothelioid and vacuolated).
3. Variola (with the gay blood picture).
4. Typhus in later stages.
5. Measles and German measles.
6. Varicella, less marked.
7. Slight in scarlet fever.
8. Less marked in parotitis epidemica, mild cases.
9. Less marked in acute syphilitic and tuberculous processes.
10. Infections and infectious diseases as a secondary finding with good prognosis.

11. Monocytic leukemia.
12. Malignant endocarditis lenta ulcerosa (macrophages).

Monocytosis with low normal to high normal count of white blood cells:

1. Chronic vascular diseases, such as severe arteriosclerosis, in recovery, especially near the crisis.
2. Chronic syphilis and tuberculosis.
3. Slight in malignant tumors.
4. Acute protozoal diseases during the attacks (malaria and trypanosomiasis).
5. Severe cases of parotitis epidemica.
6. Basedow fruste.
7. Helminthiasis.
8. Hyporegenerative septic processes as a secondary finding.
9. Agranulocytosis.
10. Banti's symptom complex.
11. Measles.
12. Yellow fever.
13. Dengue fever.
14. Spotted fever.
15. Ophthalmia sympathica.
16. Poliomyelitis.
17. Pellagra.

Decrease or absence of monocytes:

1. Very severe infections as a very unfavorable symptom.
2. Myelocytic and lymphocytic leukemias.

Chapter 66

Myeloproliferative disorders

JOHN D. BAUER

In the group of myeloproliferative disorders[721] a number of diseases are collected which may or may not be related and which at times overlap but which have the following features in common: their precise etiology is unknown, they originate in the bone marrow or other erythropoietic sites, and they are characterized by the proliferation of one or the other or of all elements which occur in the bone marrow.

In many of the previous chapters benign, reversible, or reactive bone marrow proliferation following a known stimulus such as blood loss, infection, etc., has been described. In the myeloproliferative disorders the cause is unknown, and the proliferation is progressive, irreversible, and thus malignant. The borderline of benign hyperplasia is by no means clearcut, and it is at times difficult or impossible to decide at a given time whether a proliferative process is benign or malignant.

CLASSIFICATION

- Chronic types
  - Polycythemia vera
  - Myelosclerosis with myeloid metaplasia
  - Chronic granulocytic leukemia
  - Chronic erythemic myelosis (Heilmeyer)
  - Aplastic anemia (chronic congenital hypoplastic anemia)
- Acute types
  - Acute erythremic myelosis (Di Guglielmo's disease, erythremia, erythroleukemia)
  - Acute granulocytic leukemia
  - Acute megakaryocytic leukemia
  - Acute myelosclerosis with myeloid metaplasia
  - Thrombocythemia
  - Aplastic anemia

Some of these disorders, as stated previously, are poorly delineated, poorly understood, overlap, and fade into each other so that mixed forms occur—erythromegakaryocytic myelosis, erythroleukemic myelosis, etc.

Some of the conditions classified as myeloproliferative disorders, such as aplastic anemia, myelosclerosis, and myelofibrosis, produce a clinical condition referred to as bone marrow failure, relative bone marrow failure, refractory anemia, or aplastic anemia. In some of these conditions the bone marrow morphology fails to correlate with the peripheral blood picture.

Under the heading of chronic bone marrow failure the following conditions should be mentioned: pure red cell anemia (chronic simple anemia), myelophthisic anemia, and idiopathic bone marrow failure.

APLASTIC ANEMIA

The inclusion of aplastic anemia in the myeloproliferative disorders may at first seem strange until one realizes that aplasia and hyperplasia are frequently close neighbors. The stimulated hyperplastic bone marrow in benzol poisoning may become exhausted and give way to a bone marrow devoid of blood-forming elements, whereas the hypoplastic bone marrow of acute leukemia may blossom into the hypercellular stage of fully developed leukemia.

Aplastic anemia is usually regarded as a well-defined, readily recognizable clinical entity, with features that are the result of a progressive depression and final cessation of bone marrow activity and aplasia of this tissue. Ordinarily, one does not think of regeneration in these cases, but Thompson et al.[722] reported 13 cases of aplastic anemia in which there was evidence of blood regeneration. The first case of aplastic anemia on record is that by Ehrlich.[723] In this case the red cell count was 213,000, no white cell count was reported, no blood platelets were reported, and the tibial bone marrow was yellow and fatty. By 1908 Cabot[724] had collected 24 cases, and Hirschfeld[725] in 1911 found the total to be 44. Musser[726] reviewed the situation up to 1914. In 1919, Smith collected 64 cases. He found that it was a disease of young adults that progressed rapidly and was characterized by a progressive decrease in the number of formed elements in the blood. Root[727] and Carey and Taylor collected, in 1931, 150 cases.

It is accepted that idiopathic aplastic anemia is a uniformly acute, rapidly fatal disease of adolescents and young adults, with a high fever, a rapid decrease in the cells of the blood with very little suggestion of regeneration of the blood cells. At autopsy the bone marrow shows complete fatty degeneration.

The blood picture is a lowered count, often below 2,000,000, and a marked lowering of hemoglobin. Although there is a rapid decline in the number of red cells, the form of the cells is not markedly changed. It is significant that there are no nucleated red cells and very little polychromasia. Reticulocytes are very scarce. The white cell count declines, with a decline of the neutrophils and disappearance of eosinophils, and relative lymphocytosis supervenes. There is marked leukopenia in advanced cases of this disease. The final picture, so far as leukocytes are concerned, is practically all lymphocytes. Another very characteristic phenomenon in the blood picture is the decline and absence of blood platelets. It is significant that when the blood platelets drop very low purpuric symptoms occur.

From a study of the literature, it seems that there are 3 variants of aplastic anemia. There are cases in which the disease is acute in its course, without evidence of regeneration and with complete aplasia of the bone marrow at autopsy. In addition, there is a second group comprising a few cases with clinical features similar to the preceding group, but in which the marrow, instead of being fatty, has a normal or even increased cellular content. Such cases have been reported by Naegeli,[728] Senator,[729] Wolff,[730] and Root[727] and several appear in the Italian literature[731-733] under the name of pseudoplastic anemia, a term suggested by Luzzatto[733] to indicate the discrepancy between the blood and bone marrow pictures. The third variation includes progressive hypocythemia cases in which evidence of regeneration appeared in the peripheral blood.

According to Thompson et al., examination of the peripheral blood may be no index as to the morphologic appearance of bone marrow examined, and the morphologic appearance of the bone marrow may be no index as to its functional activity. There may be quite serious interference with the normal course of development, maturation, and division of blood cells without alteration in the cellular content of the marrow.

Krumbhaar in commenting upon the case reports and conclusions of Thompson et al. stated very properly that these conditions should be described by 3 different labels as follows: aplastic anemia to be reserved for the type without evidence of regeneration in blood or bone marrow, pseudoaplastic anemia for the variety with cellular bone marrow, and progressive hypocythemia for the cases corresponding to those of Thompson et al. in which there is an evidence of attempted regeneration in both bone marrow and blood.

In summary we then distinguished the following types of aplastic anemia: primary aplastic anemia and secondary aplastic anemia.

Primary aplastic anemias

Pure aplastic anemia (pure red cell anemia): This anemia is characterized by a progressive normocytic normochromic anemia. The bone marow shows disappearance of erythroblasts and normoblasts. In the peripheral blood no evidence of red blood cell regeneration can be found, but the complement of platelets and white blood cells is essentially normal. There is no enlargement of the spleen, lymph nodes, or liver. Such anemias have been described in association with thymomas and acute renal failure and following nerve resection.

Pseudoaplastic anemia (hypoplastic anemia): The bone marrow may be cellular or even hypercellular, but because of a maturation arrest at the normoblastic level, the peripheral blood lacks reticulocytes. Splenomegaly and hepatomegaly are absent. This anemia also goes under the name of refractory anemia.

Hypoplastic anemia of Diamond-Blackfan (congenital): This anemia is characterized by a hypoplastic marrow erythropoiesis rather than by complete aplasia. It is found in newborn infants and children. It is at times associated with other congenital defects such as Fanconi's syndrome. It is interesting to speculate that a myeloid-lymphatic antagonism is etiologically involved in the production of this anemia. The existence of such an antagonism can be postulated in the pure red cell anemia associated with thymomas. In children who characteristically show hyperplasia of lymphatic tissues, a similar mechanism could be considered responsible for the production of the bone marrow depression. The hematologic findings vary from a macrocytic to a normocytic anemia, without reticulocytosis or only a minimal increase in reticulocytes.

Idiopathic aplastic anemia: This anemia shows depression of all blood-forming marrow elements: erythroblasts, granulocytic elements, and megakaryocytes. The blood picture reflects the results of marrow failure.

Secondary aplastic anemias

Secondary aplastic anemias may follow irradiation therapy or the administration of cytotoxic drugs or drugs to which an idiosyncrasy may develop.

One of the most important drugs that selectively suppresses the bone marrow erythropoiesis is chloramphenicol.[734, 735] In patients who are sensitive to this drug within 48 hr. after administration of chloramphenicol vacuolization of the erythroblastic cytoplasm appears, and the peripheral reticulocytes fall below 0.5%. If the drug is not discontinued, irreversible aplastic anemia may result.

Hematologic findings

The red blood cells show a severe normocytic normochromic anemia. The polymorphonuclear cells are at times slightly increased and may show toxic granulation. Usually there is an increase in lymphocytes and monocytes. Thrombocytopenia is usually present. The bone marrow shows hypoplasia of all elements, and if erythroid elements are seen, they may be abnormal. The megakaryocytes may be decreased or increased in number.

Nonhematologic findings in aplastic anemia

The nonhematologic findings include an elevated serum iron and an abnormal amino acid excretion pattern of the urine.

Etiology

The actual cause is unknown. The most interesting aspect of some of the aplastic anemias is the hormonal dependence exhibited by their response to therapy with steroids and testosterone.[736, 737]

Differential diagnosis

Aleukemic leukemia associated with hypocellular bone marrow may mimic aplastic anemia so closely as to be indistinguishable until immature cells are found in the peripheral blood. Bone marrow aspiration or surgical biopsy (Vim-Silverman needle) may be helpful in the differential diagnosis.

Myelophthisic anemia: The anemia is the result of replacement of the bone marrow by nonhemopoietic tissue, such as fibrous tissue (myelofibrosis, myelosclerosis), by tumors such as lymphomas (Hodgkin's disease), and by metastases of carcinoma the primary site of which is usually the lung, thyroid, breast, or prostate. The bone marrow space may also be occupied by granulomas such as tuberculosis or by reticuloendothelioses. The hemopoietic activity is taken over by the spleen and liver which develop extramedullary hematopoietic activity.

Myelofibrosis: This is an obliterative bone marrow disease of many years' duration. The liver and spleen enlarge markedly due to the tremendous hemopoietic activity (agnogenic? myeloid metaplasia). The peripheral blood picture is characterized by a severe anemia exhibiting anisocytosis, poikilocytosis (teardrop cells), and normoblastosis. Not only is there leukocytosis, but also immature white cells are swept into the blood stream, producing a picture not unlike that of chronic granulocytic leukemia. The increase in the number of platelets adds to the difficulty in distinguishing myelofibrosis from myelogenous leukemia, which at times is accompanied by marrow fibrosis. The differential diagnostic points are described in the discussion of chronic myelogenous leukemia. In addition to the hematologic consideration just mentioned, bone biopsy (needle or surgical) and radiographic examination of the bones may be helpful.

Marble bone disease (Albers-Schönberg): This disease, which begins in childhood, is characterized by replacement and finally obliteration of the bone marrow cavities by bone. The anemia is of the leukoerythroblastic type, similar to the one in myelosclerosis. The liver and spleen enlarge as they take on hematopoietic function. Diagnosis is based on the leukoerythroblastic anemia, bone marrow biopsy, and characteristic radiologic findings.

POLYCYTHEMIA (ERYTHROCYTOSIS AND ERYTHREMIA)

Table 268 shows the nomenclature prepared by the American Society of Clinical Pathologists' Committee for Clarification of the Nomenclature of Cells and Diseases of the Blood and Blood-Forming Organs.

Table 268. *The erythrocytoses**

Term to be used	*Terms to be avoided*
Erythrocytosis due to polycythemia vera	Erythremia, polycythemia, Vaquez's or Osler's disease, erythremia, splenomegalic polycythemia, Gaisböck's disease, polycythemia hypertonica, erythroleukemia, polycythemia rubra vera, erythrocytosis megalosplenica
Arterial anoxemia due to:	Erythrocytosis, erythremia, erythroleukosis
Unknown cause	
Heart disease	
Pulmonary disease	
Arteriolosclerosis in lungs	Ayerza's disease
Hereditary leptocytosis (trait)	

*From Am. J. Clin. Path. **20**:562, 1950.

Classification

Polycythemia is a term used to describe an increase in the number of circulating erythrocytes. Several types of polycythemia can be distinguished.

Relative polycythemia—synonymous with hemoconcentration produced by plasma loss leading to an increase in the red blood cells per unit volume (dehydration).

Secondary polycythemia (erythrocytosis)—characterized by in increase in red blood cells due to increased erythropoiesis secondary to chronic anoxemia.

Polycythemia vera or erythremia—a disease of unknown etiology characterized by increased production of red blood cells, white blood cells, and platelets.

Symptomatic polycythemia—erythrocytosis accompanying various primary diseases not associated with any form of anoxemia as far as it is known.

Relative polycythemia

Relative polycythemia may be caused by dehydration and may give the patient the appearance of absolute polycythemia. In this condition, however, there is a diminished blood volume but no real overproduction of red blood cells. This occurs following excessive exercise in which there has been an unusual excretion of water through the skin and lungs. Prolonged vomiting, diarrhea, and fever may be causative factors. In other words, it is due to loss of water from the blood plasma following abnormally lowered fluid intake or marked loss of body fluids (dehydration). The differential diagnosis depends upon the presence of increased red blood cells associated with diminished blood plasma volume as determined by the hematocrit. The condition is usually transitory, definite improvement occurring by dilution of the blood with fluids.

Secondary polycythemia or erythrocytosis

Secondary polycythemia or erythrocytosis usually represents an effort on the part of the organism to compensate for difficulties in the oxygenation of the blood or tissues of the body, the underlying cause of the increased blood production being oxygen want. First, there may be defective saturation of arterial blood with oxygen as evidenced by the erythrocytosis of high altitude (mountain sickness). This occurs not only in people who live in high altitudes but also in travelers who go up in planes or climb mountains. Blood counts may reach 7,500,000 or 8,000,000 cells/mm. This condition from a similar cause (that is, poor oxygenation) is also found in newborn infants, congenital heart disease, and certain forms of acquired heart disease and pulmonary diseases and in those conditions due to a defect in the hemoglobin of the blood so that it is unable to combine with oxygen in normal amount as manifested by the toxic action of various bacterial and chemical poisons on the red blood cells.

In this classification are thus such conditions as mountain sickness, chronic heart disease, cyanotic congenital heart disease, *e.g.* tetralogy of Fallot associated with shunt of venous blood into the arterial system prior to aeration, pulmonary emphysema, pulmonary fibrosis, pulmonary hypertension, pulmonary arteriovenous fistula, pulmonary artery sclerosis, certain blood diseases such as methemoglobinemia, hemolytic anemias, chronic carbon monoxide poisoning, and early stages of others such as myelosclerosis, leukemia, etc. It might be mentioned here that the recovery stage of some anemias may be associated with transitory polycythemia.

In secondary polycythemia red cell counts as high as 13,900,000 have been recorded and hemoglobin as high as 23.7 gm. (normal, 13-15 gm.), whereas the volume of packed red cells averages 54.4/100 ml. (normal, 41.9-42-9 ml.).

Polycythemia vera or erythremia

Polycythemia vera or erythremia is a slowly, intermittently progressive disease of unknown etiology characterized by a striking absolute increase in the number of red blood corpuscles and the total blood volume and frequently by signs of generally increased bone marrow activity.

Attention was called to this disease in 1892 by Vaquez some time following the development of a method for counting red blood corpuscles in the middle of the nineteenth century.

The disease is more common in males than females; a fair percentage of the cases are found in Jews born in Eastern Europe. It usually occurs in middle or late life. Several persons of the same family may be affected. The majority of workers in this field believe that the pathologic physiology is an increased activity of the blood-forming apparatus.

Patients are usually vague in their statements concerning the date of onset of symptoms. From histories of slight discomfort or vague ill-defined complaints it is evident that the disease is likely to have been present for a long time before it finally obtruded itself upon the consciousness of the patient. Individuals may apply to the physician for cosmetic reasons to be rid of the unnatural red flush of the skin and may be otherwise symptom free. Such general symptoms as weakness, lassitude, easy fatigability, loss of weight, and shortness of breath are frequently present. Various gastrointestinal symptoms including abdominal pain, eructations of gas, anorexia, nausea, and vomiting may occur. Hemorrhages into the skin and mucous membranes are not uncommon. Nervous symptoms manifested by headache, dizziness, noises in the ears, tingling sensations of the hands and feet, staggering gait, muscular weakness, blurring of vision, thickness of speech, and even loss of consciousness may be complained of.

On physical examination one finds the characteristic reddish blue color of the skin and mucous membranes, or there may be a definite pallor. The spleen is enlarged in the majority of patients; the size of the spleen varies greatly at different periods of the disease. Enlargement of the liver occurs in more than 50% of the patients. Blood pressure is usually within normal limits. Muscular twitchings or paralysis may be present. There is no enlargement of the heart in the majority of the cases. Palpitation is complained of by many patients. The disease may be latent for years. After it has become fully manifest, its course is chronic, slowly progressive, and ultimately fatal. Patients may live from 4-20 yr. or more after the onset of the recognized symptoms. Death usually results from vascular complications, especially cerebral thrombosis or hemorrhages. Serious and often fatal hemorrhages have occurred from esophageal varices or from blood vessels of the stomach, lungs, or other viscera. Heart failure may be the terminal event.

Examination of the blood reveals a marked increase in the red cell count. It usually ranges from 7,000,000-12,000,000/c.mm., the highest authentic count recorded being 13,600,000/c.mm. It has been calculated theoretically that with red cells of normal size the circulatory system would be unable to contain the blood if the count exceeded 13,900,000/c.mm. The blood is characteristically dark and spreads slowly under the cover glass. It may be so thick that it is drawn up into a pipet with difficulty. Patients with 80 ml. packed red cells/100 ml. blood have been observed.

In polycythemia the red blood cells are often normal in size, but it is not uncommon to find that their mean volume is less than normal. Thus the average size in 14 cases was 83 cμ—the smallest cells being about 61 cμ.

The hemoglobin is also increased but less than the red cells. Hemoglobin values varying from 18-24 gm.% are common.

The blood counts vary appreciably from day to day; spontaneous remissions and relapses occur. Simultaneous blood counts from venous and arterial blood show in general no marked differences.

The red blood cells as examined in the blood spread may appear quite normal; however it is not unusual to find somewhat greater variation in size than is normal and more rarely, poikilocytosis. Microcytes are not infrequent; macrocytes are unusual. Especially when the disease has become more advanced and particularly when hemorrhage has occurred, the red cells appear paler than normal. Polychromatophilia and less frequently basophilic stippling may be encountered. Nucleated red cells are not rare, but other indices of increased erythrogenesis are almost never encountered. Anisocytosis, poikilocytosis, polychromatophilia, and normoblastosis may be quite marked. Special staining reveals frequently a slightly increased reticulocyte count, often about 1-2%. Increases in reticulocytes are found following hemorrhages only.

Leukocytosis is quite common, the count varying from 10,000-25,000, but values up to 50,000/c.mm. are by no means rare. The leukocytosis is due to an absolute increase in the number of granulocytes. The cells of the myeloid series comprise 70-95% of the leukocytes. Metamyelocytes are found in increased number, and it is not unusual to find 1-2% myelocytes; myeloblasts have also been observed. The eosinophilic and basophilic leukocytes may be increased although this is less common. Lymphocytes are relatively reduced, but usually their absolute number is about normal. Monocytes may be absolutely increased.

The blood platelets are usually increased; counts of 1,000,000/c.mm. are quite usual, and in some cases the count may exceed 3,000,000. Megakaryocytes are rarely found in the circulating blood.

Bleeding time is usually essentially normal, and coagulation time is normal. Clot retraction may be slow. The poor clot retraction has been related to the increased number of platelets, but recently Abraham et al.[738] found evidence of a platelet factor 3 deficiency. Disturbances in fibrinogen contents and deficiencies of factor V and factor VII have been reported.

Fragility of the red cells may be normal but is frequently increased. In dilutions of their own or normal serum, the patient's cells might yield an abnormally long resistance span. Normal cells however may be hemolyzed in dilutions of the patient's serum.

The viscosity of the blood in polycythemia is much greater than that in normal blood. It may be 5-8 times greater. This is due primarily to the great excess of red blood cells over plasma. The viscosity of the serum, indeed, is said to be less than is normally found in health. Likewise the specific gravity of erythremic blood is 1.075 to 1.080 as compared with 1.055 to 1.065 for normal blood. The sedimentation rate of polycythemic blood is very greatly delayed.

The total volume of blood in erythremia as measured by both the dye and carbon monoxide methods is found to be greatly augmented. Volumes of 121-246 ml./kg. body weight have been found as compared with a normal value of 87 ml. Plasma volumes are increased little or not at all. There is an increase in the blood in the organs in general, and even the smaller vessels of the pia mater of the brain and cord are engorged and distended with blood.

Sternal bone marrow puncture reveals a dark red marrow crowded with enormous numbers of mature erythrocytes as well as with normoblasts. All the nucleated red cells are small and contain round, ripe, often pyknotic nuclei. Proerythroblasts are frequently few or absent. Polychromatophilic red cells are few. The leukopoietic apparatus is also overactive, with myelocytes and metamyelocytes predominating; even the promyelocytes may be increased in number. Mature neutrophils are reduced in number. Megakaryocytes are frequently increased.

Complications: The most important complications are vascular in type. There is frequent (about 30%) occurrence of thrombosis, which may involve the extremities, the cerebrum, the heart, or of course other sites. About 10% of all patients develop peptic ulcers which may well be a thrombotic phenomenon. The other vascular phenomenon is hemorrhage. The slight coagulation defect coupled with congestion and distention of the vascular bed leads to hemorrhage, mainly from the mucosa of the gastrointestinal tract.

Gout is a somewhat infrequent complication though moderate hyperuricemia is commonly found. The latter is more marked if myelosclerosis and myeloid metaplasia are associated with polycythemia.

The ultimate fate of some of these patients is responsible for the inclusion of polycythemia vera among the myeloproliferative syndromes. It is stated that 20-60% of the patients with polycythemia, if they survive a period of approximately 10 yr., will die with signs and symptoms of chronic granulocytic leukemia or erythroleukemia. About 30% of these patients develop myelosclerosis characterized by an enlarged spleen and immature red and white cells in the peripheral blood (myeloid metaplasia). These terminal changes are not the result of treatment with P^{32} or radiation since they were seen before the advent of P^{32}. A further proof of some pathophysiologic relationship between polycythemia, leukemia, and myelosclerosis lies in the fact that primary myelosclerosis may initially show a polycythemic blood picture. A few cases of pernicious anemia have been reported which terminated as polycythemia vera. In some of the cases reported as granulocytic leukemia following polycythemia vera, the alkaline phosphatase content of the white cells was not decreased as is expected in granulocytic leukemia but rather was elevated. Some of the cases reported as myelogenous leukemia may thus in fact represent examples of extreme granulocytic hyperplasia. There is evidence that elevation of the serum lactic acid dehydrogenase will foretell the leukemic termination of polycythemia vera.

Ferrokinetics of polycythemia vera: There is an increased plasma iron turnover. The iron disappears rapidly from the plasma and is rapidly incorporated into the red cells. The daily hemoglobin synthesis in polycythemia vera is several times the normal rate.

Pathogenesis: As stated, the cause of polycythemia vera is unknown. Neither anoxemia, central stimulation, nor overproduction of erythropoietin can be accepted as the etiology. The many reported cases of polycythemia associated with renal disease proved, on detailed examination, to be instances of erythrocytosis rather than polycythemia, and are included in the discussion of erythrocytosis. The final leukemic stage of polycythemia brings to mind Dameshek's concept of an "acquired self-perpetuating metabolic defect due to enzyme deletion," which he considered to be an etiologic possibility in Di Guglielmo's disease.

Treatment of polycythemia: Dameshek[739] gave an excellent summary of the present concept concerning the treatment of polycythemia.

The treatment of polycythemia has passed through several successive stages since Osler first used benzol to reduce the excessive blood cell formation. Phenylhydrazine, a hemolytic poison, was introduced by Morawitz following its experimental use by J. H. Pratt. Although this new drug achieved wide popularity, its unpredictable nature and the severe hemolytic crises which often ensued made its use relatively hazardous.

In Dameshek's experience, the removal of 500 ml. blood twice weekly for 2-5 wk., depending upon the initial hematocrit and hemoglobin levels, has proved a satisfactory method. To maintain somewhat longer the resulting state of iron deficiency, it has been his practice to keep the patient on a diet low in iron. Red cell formation under these circumstances is only partially reduced, but hemoglobin and hematocrit levels remain low for periods of 6-18 mo., during which time the patient may be completely asymptomatic. Red cell levels during this induced remission gradually rise so that the red cell count as an index of therapy is of little value. The best index is the hematocrit value although the hemoglobin concentration alone may be used since this correlates fairly closely with the hematocrit level. With this method of therapy patients go along for many years with very little more difficulty than do others in the older age group in which polycythemia occurs.

The use of x-ray therapy has in Dameshek's hands proved ineffective, either by heavy dosage to localized areas or by spray or generalized therapy. He has hesitated to use high voltage x-ray in these essentially normal individuals because of the possible dangers of radiation malignancy or leukemia. The introduction of radioactive phosphorus, as discussed by Erf,[740] makes therapy a good deal easier and is ordinarily productive of an excellent remission.

Symptomatic polycythemia

In symptomatic polycythemia the relationship between red cell volume and plasma volume remains normal. There is no splenic tumor.

The etiology of many of these erythrocytoses is unknown, and they usually show only a rise in the red blood cells.

Polycythemia of stress: Dameshek[741] described this well-accepted entity in 1953. These individuals are usually men of the plethoric, obese, aggressive type with elevation of blood pressure. Acrocyanosis of the hands and feet may be present. Other than an elevation of the red blood count and hematocrit, all hematologic data are normal. Arterial oxygen saturation is normal, bone marrow studies are normal, and the red blood cell volume is normal. Plasma volume, however, is low. Lawrence and Berlin[742] emphasize the low plasma volume and suggest that it may be the result of long-continued psychic stress. These patients have such disturbances as peptic ulcer, coronary disease, and hypertension, a triad familiarly associated with psychosomatic disturbances. Dameshek stresses recognition of this entity, chiefly to avoid the type of vigorous therapy traditionally given patients with polycythemia vera.

Erythrocytosis associated with tumors: The following tumors have been seen associated with polycythemia: cerebellar hemangioblastoma, hypernephroma, uterine fibroids,[743] and cardiac myxoma. Pathophysiologic pathways may include erythropoietin production, intravascular erythropoiesis, or diencephalic stimulation.[744]

Erythrocytosis and kidney diseases[745]: Apart from the aforementioned renal cell carcinomas, erythrocytosis has been linked to hydronephrosis, renal cysts, adenomas, metastatic tumors to the kidney, and renal tuberculosis. It appears most attractive to make the increased production of erythropoietin responsible for the erythrocytosis.

Erythrocytosis and endocrinopathies[746]: Cushing's syndrome is usually accompanied by an increase in circulating red blood cells. If one accepts the hypothalamic etiology of Cushing's syndrome, the erythrocytosis may be classified as cerebral in origin, similar to the one seen in some cases of encephalitis or brain tumors. If the spleen can be classified as a hormone-producing organ, the increase in red cells accompanying splenic tuberculosis or hyposplenism may fall into this category.

Laboratory diagnosis of polycythemias

The differential diagnosis[747] of the polycythemias is presented in Table 269.

Bioassay of erythropoietin[748]: Methods to measure erythropoietin utilize live rats which are rendered sensitive to the action of exogenous erythropoietin contained in the assay material, such as human plasma, serum or kidney tumor extracts, kidney cyst fluid. The endogenous erythropoietin of the rat is suppressed by various procedures such as starvation, transfusion polycythemia, hypophysectomy, and others. Fe^{59} is used to measure changes in red cell production.

DI GUGLIELMO'S SYNDROME

This disease is among the many myeloproliferative disorders. It represents a primary disease of the erythropoietic bone marrow. It is divided into 2 groups: acute erythremia (Di Guglielmo's disease) and chronic erythremia (Heilmeyer-Schöner disease).

Acute erythremia (Di Guglielmo's disease)

Clinically, this disease is characterized by an acute onset, by severe anemia, and by hemorrhagic and hemolytic manifestations.

Hematologic findings:

Red blood cells: There is a severe progressive normochromic or hypochromic hemolytic anemia characterized by a diminished number of red blood cells, associated with a low hematocrit and hemoglobin values. The peripheral blood film shows anisocytosis, poikilocytosis, and macrocytosis. Numerous erythroblasts are seen, mainly basophilic early forms and relatively few more mature erythroblasts. Many of the erythroblasts are pathologic and show irregular lobulated nuclei, with evidence of abnormal nuclear cytoplasmic maturation and ratio.

White blood cells: The white blood cell count is normal to diminished or slightly increased.

Platelets: Platelets are always diminished.

Bone marrow: Most normal bone marrow elements are crowded out by erythroblastic hyperplasia characterized by predominance of basophilic erythroblasts over the more mature erythroblasts. Megaloblasts and giant erythroblasts are seen as well as pathologic multinucleated and multilobulated erythroblastic forms.

Nonhematologic findings:

Plasma: The plasma vitamin B_{12} level

is elevated, and there is evidence of hemolysis.

Pathology: Di Guglielmo states that the main pathologic disorder lies in the erythropoietic system which shows hyperplasia (increase in number of erythroblasts) accompanied by anaplasia of the erythroblasts (inability to mature) and dysplasia (nuclear and cytoplasmic abnormalities). For a short discussion of etiologic concepts see the final paragraph of the section on pernicious anemia.

Course of disease: The disease is a myeloproliferative disorder, and true to form as it progresses, evidences of acute leukemia may appear (erythroleukemic form). Finally the picture may become one of pure acute myelogenous leukemia.

Chronic erythremia (Heilmeyer-Schöner disease)

This disease is similar to the acute form though clinically it is of longer duration and is less aggressive. Hematologically it is more dysplastic than anaplastic (the words dysplasia and anaplasia are used in Di Guglielmo's sense, see discussion of acute erythremia).

Mixed forms

In the evolution and course of acute erythremia various mixed forms occur. These conditions are self-explanatory and were named by Di Guglielmo as follows: erythroleukemia, erythromegakaryocytic leukemia, and erythroleukomegakaryocytic leukemia.

The morphologic features of these diseases are by no means clear-cut, and the characteristics of each overlap to such an extent that it is at times difficult to establish a definitive diagnosis. Not only is there some difficulty in delineating these subgroups, but it is also at times difficult to establish the diagnosis of Di Guglielmo's disease. The differential diagnosis includes not only acute and chronic leukemia with symptomatic erythroid hyperplasia, but, more important, also myelosclerosis, severe hemolytic anemias, polycythemia, and pernicious anemia. Such laboratory procedures as serum iron determination, stain for alkaline phosphatase in polymorphonuclear cells, serum level of vitamin B_{12}, and surgical biopsy of bone marrow may all be helpful in the differential diagnosis.

LEUKEMIA

The historical development of leukemia might be said to begin with a description of the disease by Virchow in the eighteen fifties, when he outlined the "lienal" and "lymphatic" forms of leukemia. Between 1875 and 1877

*From Am. J. Clin. Path. **20**:571, 1950.

Virchow differentiated leukemic cell increase from the leukocytoses due to pus formation. With the advent of selective stains into hematology there began recognition of the difference between the lymphocytic and myelocytic leukemias. Then came Naegeli's characterization of the myeloblast which gave this dualistic conception of the disease a firm basis. With the final appearance of the oxydase reaction, it was possible to differentiate myelocytic from lymphocytic cells histologically.

What is leukemia? Leukemia has many features of a malignant neoplasm. The progressive, purposeless growth of the leukemic cells, leading to the death of the patient, is good evidence for the autonomous nature of this disease. In animals, as in man, leukemia may be but one phase of tumor growth. Several years ago (1953) Custer showed the interrelationship of lymphosarcoma and Hodgkin's disease on the one hand and lymphatic and monocytic leukemia on the other hand. The endothelioma of fowl, after many passages, becomes leukemia, and fowl leukemia after many passages will become sarcoma.

Leukemia or at least some forms of it may be of a nonneoplastic nature. The evidence is meager. Leukemic cells fail to grow in the anterior chamber of the rabbit eye, which allows growth of most other human tumors. This behavior may be related to some specific environment these cells require.

Leukemia may be a viral disease.[749] Animal experimentation strongly favors this view. Electron microscopic pictures of chicken leukemic cells reveal viruslike particles. In animals leukemia can be transferred by means of cell-free filtrates from a high leukemic strain to a low leukemic strain. Viruslike inclusions have been reported in human leukemias. Injection of urine of leukemic patients into high leukemic mice strains will give rise to leukemia.

Ellermann has described a chicken leukemia which may be transferred by means of a filtrable virus but which alternately shows myelocytic, lymphocytic, and erythropoietic hyperplasias. Snijders[750] reported, in 1926, a large cellular leukemia of a guinea pig. One hundred forty-eight other guinea pigs which were inoculated with living cells from the first pig developed leukemia; some showed tumorlike infiltrations, some highly tumorous leukosarcomatosis, etc. The proliferating cells all seemed to originate from the transplanted foreign cells.

Leukemogenic factors:

Heredity: Some strains of mice (AKR mouse) show a high incidence of leukemia, whereas others rarely develop leukemia. In human beings and in higher animals there are reports of familial predisposition.[753] A genetic factor[754] is also suggested by the association of acute leukemia and mongolism, a disease which shows an abnormal chromosomal pattern.

Exposure to radiation[755]*:* Two separate problems must be considered—the short more or less single exposure to large amounts of irradiation and the repeated exposure to small doses of radiation. Hiroshima and Nagasaki provided the answer to the problem of massive exposure. The problem of the leukemogenic effect of therapeutic or diagnostic irradiation, as well as of the increased radiation background, has not been settled yet, but there is some evidence that increased exposure to x-ray increases the incidence of leukemia.

Studies[751, 752] on people exposed to atomic bomb radiation in Hiroshima and Nagasaki revealed 75 cases of leukemia, indicating a great increase in incidence of this disease in the survivors of this exposure. The predominant form was chronic myelocytic leukemia, but it has been pointed out that lymphocytic leukemia is rare in Japan. The leukemogenic effect of ionizing radiation was distributed equally in all age groups and in both sexes. In some of the cases there was a prolonged latent period of several years before development of the disease. In these preclinical stages, disturbances of the red cells and platelets as well as of the leukocytes were noted. An increase in basophils, many of which were abnormal, was one of the outstanding features. Lange, Moloney, and Yamawaki hypothecate that disturbances in cell enzyme systems with a resultant loss or alteration of cell growth-promoting or regulating factors account for the leukemic changes.

10.2	6.2	0.6	1.4	2.2	0.4	0.6

Incidence: All statistical figures point to an increase in leukemias.[756] Part of this increase is accounted for by improvement in diagnosis and part of it is due to the increasing percentage of older people in the population who fall victim to chronic lymphatic leukemia. There still remains the increased frequency of acute leukemia in the ages between 2 and 5 yr.[757]

Red cells and hemoglobin in leukemia: Naegeli states that polycythemia is always present in mild cases of leukemia, but this is only for a very brief period. Anemia appears, with hemoglobin falling to 60% and red cells decreasing to 3,000,000. As the disease progresses, the anemia becomes more severe. There is an increase in reticulocytes, and many normoblasts appear in the picture. The anemia may be due to crowding out of the erythrocytic elements by the proliferating white cells, or it may be due to hemolysis or hemorrhage. Bone marrow depression, hypoplasia, or maturation arrest are seldom responsible for the anemia, but if they are present, they are due to hypersplenism. Granulocytic leukemia seldom gives rise to autoimmune hemolytic anemia which is frequently seen in chronic lymphatic leukemia. Hemorrhage is seldom an important feature of chronic leukemias.

In the terminal stage of chronic myelocytic leukemia the anemia becomes more marked, as a result of which the patient usually dies. The picture at this point is very much like that of a true pernicious anemia.

Types: There are 2 main types of leukemia—acute and chronic. This classification is based not only on the clinical course but also on the histologic cell type, the more immature forms being associated with the acute forms of leukemia. It is obvious that in some cases the clinical course will belie the histopathologic classification. It is customary to classify the leukemias further on the basis of the predominating cell type into 3 classes: (1) myelocytic (granulocytic), (2) lymphocytic, and (3) monocytic. Other forms of leukemia have also been described: plasma cell leukemia, basophilic leukemia, eosinophilic leukemia, megakaryocytic leukemia, hemocytoblastic leukemia, stem cell (blast cell) leukemia, and erythroleukemia. As will be shown later, these last diseases are subgroups of the main types of leukemia.

On the basis of the number of leukemic cells found in the peripheral blood, leukemia can be divided into leukemic, subleukemic, and aleukemic forms. In the leukemic form there is leukocytosis showing numerous abnormal cells. In the subleukemic form there is leukopenia but a number of leukemic cells can be seen, whereas in the aleukemic form there is leukopenia, and no leukemic cells can be found in the routine peripheral blood film. A buffy coat preparation would probably reveal their presence.

Chronic leukemias

Chronic myelocytic leukemia

Hematologic findings: Chronic myelocytic leukemia is characterized by highly active hyperplasia of the bone marrow which floods the blood stream with all the varieties of mature and immature leukocytes of marrow origin. In this disease there are a great many white cells, chiefly the immature forms of the granular leukocytes, together with a progressive anemia showing many varieties of nucleated red cells. The name leukemia was given by Virchow to this disease because of the appearance of the blood at autopsy, namely, whitish, but this appearance is never seen during life.

The total white count is usually about 100,000/c.mm., but it may go as high as 1,000,000. When the count is very high, it is necessary to use the red blood counting pipet in making the white count.

The differential count of leukocytes varies in different patients. The neutrophil is the predominant cell in some cases, but this is not always true. Eosinophilic leukocytes are constantly increased in actual numbers and percentage. Basophils may be increased up to 10-15% of a high total count. Myelocytes are always present; usually they are numerous, sometimes forming one-half of the total white cells in the blood picture. The greater the blood count, the greater are the number of myelocytes, especially in the later stages of

Eosinophilic segmented cells	*Neutrophilic myelocytes*	*Neutrophilic juvenile cells*	*Neutrophilic stab cells*	*Neutrophilic segmented cells*	*Lymphocytes*	*Monocytes*	*Other cells*
3.8	16	12	8.6	36	0.8	1.0	0.2

the disease. Most of the myelocytes are neutrophilic, but there are usually eosinophilic and basophilic myelocytes as well. About 3-5% of the cells in the differential count are myeloblasts, with a few promyelocytes. There are usually less than 5% of lymphocytes in the total count. There may be an occasional monocyte. The myelocytes are often atypical, varying in size and number of granules. Often the neutrophilic myelocytes retain the blue-staining cytoplasm which designates younger cells. There are many intermediate forms between the myelocyte and the stab cells in this disease. These intermediate forms are called juvenile cells, but many of them are atypical. With the oxydase stain, one can easily recognize just how many cells in the blood film are myeloid in origin.

The white cells in granulocytic leukemia have a very low alkaline phosphatase and glycogen content, as proved by histochemical stains. Some of the myeloblasts may contain Auer bodies.

Rarely chronic granulocytic leukemia occurs in childhood.

The white cell count in the terminal stage may approach a normal figure due to complete asphyxiation of the bone marrow function. In the terminal stage increasing immaturity in cell forms is seen. So many myeloblasts are seen that the picture suggests an acute myeloblastic leukemia.

It must be remembered that transitions from a chronic myelocytic blood picture to an acute myeloblastic one will occur and are connected with unfavorable changes in the course of the disease. A relapse or a terminal condition in chronic leukemia is usually attended with an acute blood picture.

Remissions are spontaneous. Apparent recoveries take place in leukemia. These remissions seem to date from the appearance of some intercurrent infection such as pneumonia, erysipelas, or purulent infection and sometimes tuberculosis. It seems likely that in the presence of a stimulus to leukocytosis the marrow reverts for a time to normal and orderly leukopoiesis, returning later, of course, to its leukemic tendencies. These remissions sometimes last several months, but one must not be deluded into the thought during this period that the patient has been cured. Total count may drop from several hundred thousand to a normal figure following an acute infection, but sooner or later the count insidiously begins to rise. Later on, with the end of the remission, the total count rises, and the differential count becomes as characteristic as it was before. The red cell count, however, does not ever become normal during a remission.

Blood platelets: Blood platelets are increased to high figures. Minot and Buckman[758] reported as high as 2,000,000 blood platelets/c.mm. The blood platelet count drops in the terminal stage. It must be assumed that these platelets are functionally inadequate (thrombocytopathy), as patients may bleed despite the high platelet count.

Making differential count of blood in myelocytic leukemia: To make a differential count of blood in myelocytic leukemia, construct a recording sheet as shown on p. 1357 and proceed to count 500 leukocytes. The method of counting blood of cases of myelocytic leukemia is given here as a suggestion to enable technicians to make these counts with the least possible difficulty. Use the 4-field meander method of Schilling (p. 1157), counting 125 cells in each of 4 fields, and record the count in the usual way, extending the hemogram as shown in Table 272.

In reporting the count, divide the total results by 5 to convert to % or the number of different types of cells in 100 leukocytes. Forms of reports vary in different institutions, but where no laboratory form is at hand, the following is suggested (Table 271).

For every 100 leukocytes counted there were 0.8 megaloblast, 1 with karyorrhexis; 1.6 macroblasts, 2 with karyorrhexis; 8 normoblasts, 3 with karyorrhexis. One erythroblast in mitosis was found on the slide, and there were marked polychromasia, slight anisocytosis, and enlarged blood platelets.

Nonhematologic laboratory findings:

Basal metabolic rate: Marked elevation without evidence of thyroid disease.

Urine: Increase in uric acid.

Plasma: Increase in uric acid level; high serum level of vitamin B_{12}.

Differential diagnosis: The diagnosis of chronic granulocytic leukemia may at times be rather difficult, especially in the early stages of the disease.

The differential diagnosis includes the following: (1) myelophthisic anemia with or without myeloid metaplasia of the spleen (myelofibrosis, myelosclerosis, carcinomatosis), (2) agnogenic myeloid metaplasia, and (3) severe leukemoid reactions.

Helpful differentiating laboratory findings:

1. Level of total white blood cell count. This is highest in granulocytic leukemia.

2. Shift to the left in the differential count. This is usually more marked in granulocytic leukemia.

3. Alkaline phosphatase stain. Alkaline phosphatase is normal or increased in leukemoid reactions and in myelophthisic anemia.

Chronic myelocytic leukemia

Chronic lymphocytic leukemia

Fig. 443

Alkaline phosphatase is decreased or absent in leukemia.

4. Shape and size of red blood cells. In granulocytic leukemia and in leukemoid reactions the red cells are usually normocytic and normochromic.

5. Bone marrow aspiration or surgical biopsy. This is the best way to establish the diagnosis of myelophthisic anemia.

Chronic lymphocytic leukemia

Chronic lymphocytic leukemia is a disease of middle and later life rare under 20 yr. of age and most common after 50 yr. of age. The pathologic change is in the lymphatic tissues. The spleen is not usually as enlarged as in myelocytic leukemia. The spleen is engorged with lymphocytes and often shows areas of infarction. The bone marrow shows replacement of fat and of normal red cell and myeloid cell tissues by lymphocytic infiltration. The lymph nodes of the entire body are enlarged, including not only the superficial glands of the neck, axillae, groins, etc., but also the lymphoid follicles of the nasopharynx, tonsils, tongue, and gastrointestinal tract. The retroperitoneal and mediastinal nodes are often enlarged and cause symptoms by pressure. An anemia is present due to the crowding out of erythropoietic tissue by the lymphocytes. There is relative neutropenia.

The white cell count varies from 50,000-1,000,000, with an average of 100,000/c.mm. Eighty per cent or more of the cells in the differential count are lymphocytes of approximately the same size.* The remaining cells are neutrophils, including myelocytes, with a few eosinophils, basophils, or monocytes. Lymphoblasts and abnormal lymphocytic forms are seen in acute relapses. The red cell changes are those commonly seen in anemias associated with myelogenous or lymphatic dyscrasias. The blood platelets are reduced, and there is a slight prolongation of bleeding time.

Lymphocytic leukemia is likely to show a transition of the blood picture to the aleukemic state or even the acute state just as is seen in myelocytic leukemia. This occurs spontaneously, during the course of treatment, or because of the onset of an intercurrent infection.

Rather important is the benign asymptomatic form of chronic lymphatic leukemia in elderly patients. Only the peripheral blood may show leukemic changes, whereas the bone marrow remains normal.

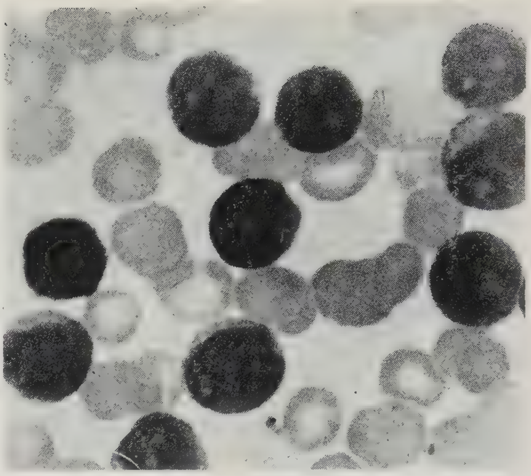

Fig. 444. Lymphocytic leukemia, blood film, showing crowding of lymphocytes. (×950.)

Nonhematologic findings: Abnormal proteins are frequently found in chronic lymphatic leukemia. The fibrinogen level and the titer of circulating fibrinolysins may be increased. The gamma globulin may show variation, extending over the entire spectrum of hypogammaglobulinemia to hypergammaglobulinemia. Autoimmune antierythrocytic and antileukocytic antibodies are frequently present, the first accounting for the hemolytic anemia commonly found in the disease. The occurrence of macroglobulins and cryoglobulins may make the differentiation from macroglobulinemia and from chronic plasmocytic leukemia somewhat difficult. The serum albumin and the antibody-producing fraction of the gamma globulins are usually decreased, leading to frequent infections and hemorrhages (even in the face of hypergammaglobulinemia). The basal metabolic rate suggests hypermetabolism.

Acute leukemias (myelocytic, lymphocytic, and monocytic)

Friedreich[759] reported a case of leukemia with an acute course. Ebstein[760] in 1889 described the clinical picture of acute leukemia. Fraenkel[761] in 1895 called attention to changes in the cells in the blood and claimed that all acute leukemias were of lymphatic origin because of the similarity of the cells to lymphocytes. Naegeli[762] in 1900 first described the myeloblast, furnishing the first data on which to classify 2 types of leukemia, myelocytic and lymphocytic. It remained for Schilling and Reschad[763] in 1913 to describe their classic

---

*The monotonous blood picture.

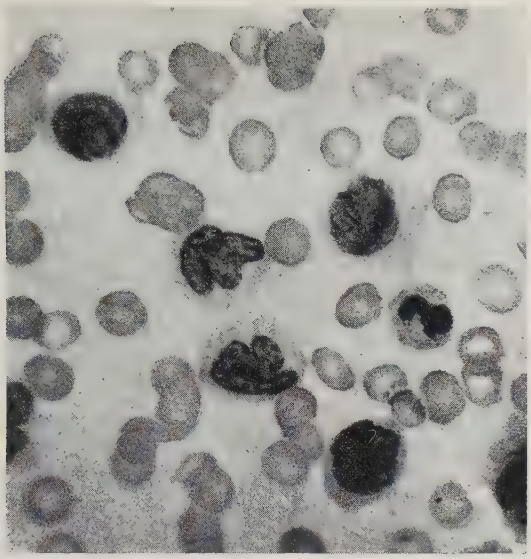

Fig. 445. Monocytosis, blood film, showing large number of monocytes. (×950.)

case of acute monocytic leukemia. This is considered the first case of this type reported or the first case of reticuloendotheliosis, as some prefer to call it. Up to the time of Clough's report in 1932[764] but 23 cases had been cited. In February, 1934, Forkner[765] reported that during the past 2 yr. 16 more cases of acute leukemia had been studied at the Thorndike Laboratory of the Boston City Hospital; these 16 cases were divided into the 3 main types—myelocytic, lymphocytic, and monocytic (6 of the last). Post-mortem examinations were made in 4 of the 6 cases of monocytic leukemia; 1 case of myelocytic and 1 case of acute lymphocytic leukemia were included with autopsy findings.

Forkner called attention to certain clinical differences between acute monocytic and other forms of acute leukemia. He insisted that the clinical picture of diffuse, marked swelling of the mucous membranes, particularly of the gingivae usually with ulceration and necrosis, is characteristic of acute monocytic leukemia and is usually absent in acute leukemia of the other types. There was diffuse cellulitis around the lesions of the mucosa, causing swelling and pain with signs of acute inflammation extending into the deeper tissues of the face. It was for this reason **that all these patients with monocytic leukemia reported by Forkner consulted a dentist early in the course of their illness.** Although acute lymphocytic and myelocytic leukemia often have mouth lesions, they are different, consisting of hemorrhages and slight infection, not necrosis. This fact stands out prominently in the 23 cases reported by Clough[764]: 18 had marked stomatitis or pharyngitis and abscesses of the alveoli, and 4 had swelling of the neck. Forkner studied the case histories of 8 additional cases which were not accepted by Clough. Three cases reported by Ewald, Frehse and Hennig[766] in 1922, 1 additional case by Bingel[767] in 1916, 1 case by Dias[768] in 1930, 1 case by Hittmair[769] in 1930, and 2 cases by Asselstine[770] in 1932 showed lesions of the mouth similar to those seen in the other 18 cases tabulated by Clough.

There are other physical signs which serve to differentiate these cases. The spleen is somewhat enlarged but is not palpable in acute myelocytic leukemia, but in the acute lymphocytic type it is palpable 2-3 cm. below the costal margin. The spleen in acute monocytic leukemia according to Clough was palpable in 16 of the 23 cases recorded by him. In Forkner's 6 cases the spleen was palpable from 1-4 cm. below the costal margin. The weight of the spleens in the 4 cases studied by him at autopsy were 1065, 606, 360, and 900 gm., respectively.

The size of the lymph nodes should be used as an aid in the diagnosis of the type of acute leukemia. Forkner claims that there is invariably an enlargement of the lymph nodes in acute lymphocytic leukemia, but it is not as marked as in chronic lymphocytic leukemia. The lymph nodes, particularly those in the neck, may be slightly or moderately enlarged in acute monocytic leukemia, but we never see the enlargement in this disease that occurs in the acute lymphocytic type. There is only a negligible enlargement in acute myelocytic leukemia.

Acute leukemia in children is often accompanied by joint pains.

The clinical and histologic differentiation of the 3 types may be seen by studying Table 273, arranged by Forkner.

The characteristics above set forth will help the differential diagnosis, in the absence of a clear-cut blood picture or histologic study of the tissues at autopsy.

Blood picture: There has existed considerable confusion as to the cytology found in these 3 types of acute leukemia. This is enhanced by the fact that as many as 85% of the leukocytes in any case of acute leukemia are of a uniformly immature type, usually in the myeloblast, lymphoblast, or monoblast stage of development. Intermediate stages are few. There are, too, some immature types

Table 273. *Clinical and histologic differentiation of three main types of acute leukemia*

	Acute myelocytic leukemia	*Acute lymphocytic leukemia*	*Acute monocytic leukemia*
Spleen	Usually not palpable	Almost invariably significantly enlarged	Palpable in about 70% of cases
Lymph nodes	Usually slight or no enlargement	General enlargement of moderate or marked degree	Moderate in neck, but other lymph nodes very slightly enlarged, if at all
Liver	Usually palpable	Usually palpable 1-4 cm. below costal margin	Usually palpable 1-4 cm. below costal margin
Mucous membranes, particularly of mouth and pharynx	Petechiae, bleeding; often slight swelling of gingivae but rarely ulceration	Petechiae, bleeding; rarely ulceration	Petechiae, bleeding; usually marked, diffuse swelling of gingivae or pharynx with ulceration; often cellulitis with swelling and tenderness of face; marked fetor oris
Oxydase reaction	From few to many oxydase-positive cells, with from few to many coarse granules	All lymphoid cells oxydase-negative	
Histologic distinctions of type cells in blood and tissues Other characteristics	Dominant-cells myelocytes A (Sabin) and myeloblasts; nuclei round or oval, usually with several nucleoli; cytoplasm deeply basophilic; myelocytes B (Sabin) present; Auer bodies frequently present in few cells	Dominant cells lymphoblasts and young lymphocytes; nuclei round, oval, or slightly indented, with few nucleoli usually present; relatively small amount of deeply basophilic hyaline cytoplasm; mature lymphocytes present in fair number; occasional myelocytes C (Sabin) and metamyelocytes present	Dominant cells monoblasts and premonocytes; nuclei usually elongated and folded, deeply indented, or otherwise irregular in contour; nucleoli rarely present; cytoplasm relatively abundant, usually not deeply basophilic and not hyaline but slightly basophilic and ground-glasslike; Auer bodies may be present in few cells; mature monocytes present in significant and varying numbers; myelocytes C and metamyelocytes often present in small numbers

present other than those of the typical leukemia with which we are dealing. Sabin,[771] Simpson,[772] and others, however, have rediscovered a method of aiding in the recognition of these cells, namely, the supravital method. One must not forget, too, that the oxydase test, as used by Schilling and his followers, is of paramount importance in this regard. Forkner, with illustrated charts of cells found in patients, called attention to some striking points of identification in regard to myeloblasts. The nuclei are round, indented, or oval and contain several nucleoli. The cytoplasm is basophilic and of uniform character. The cells in monocytic leukemic cases are more mature and possess nuclei of complicated characteristics, with very few nucleoli; their cytoplasm is relatively abundant, is basophilic, and contains dustlike granules.

Histologic differentiation of acute leukemias: The oxydase test for blood cells is a method for the differentiation of the tissues at autopsy in all leukemias. This is a helpful criterion for the pathologist. Cells infiltrating the liver, kidney, etc., if oxydase-positive point to the myelocytic character of the case. If they are oxydase-negative, it is a case of lymphocytic leukemia or lymphoblastoma. In monocytic leukemia the oxydase reaction may be positive or negative. Forkner calls attention to certain definite means of distinguishing monocytic cells in paraffin sections. Under the oil immersion objective, they show characteristics that will distinguish them from myeloblasts or lymphoblasts. The nuclei even of promonocytes and of some monoblasts are irregular in shape, in the form of an irregular crescent or a broad elongated nucleus bent upon itself. The nucleus is bent on itself several times, giving the impression of lobulation. This point made by Forkner is very impressive, especially since he has so insistently called attention to the "lobulation" of the nuclei of monocytes. May it not be true that this is not a lobulation but a pseudolobulation, as pointed out by Forkner? Distinct separation of the lobules is not demonstrable, in contrast to the ease with which it is seen in the segmented neutrophil. There are also many young monocytic cells, with simple round, oval, or slightly indented nuclei, but these cells exist as close companions of the cells with the more complicated nuclei as described. Furthermore, there are other characteristics which serve to distinguish the monocytic cells from the early lymphoid and myeloid elements. The nuclei of the monocytic series of cells rarely have demonstrable nucleoli, whereas these structures are common in lymphoblasts and myeloblasts. The cytoplasm of promonocytes and monoblasts is as a rule more abundant and much less basophilic than that of either lymphoblasts or myeloblasts and frequently it is so faint, with hematoxylin, that the border of the cell is barely recognizable. This is in contrast to the moderate or very deep basophilia of early lymphoid and myeloid cells.

In reference to the terms acute and chronic lymphocytic leukemia, Wiseman[773] has introduced the thought that from a hematologic point of view responses of the lymphatic tissue vary to such a degree that the terms acute and chronic are inadequate to express this change. Neither do these terms take into account the important relationship of lymphosarcoma to leukemia. "Finally," he states, "there does not appear to be any justification for the term 'aleukemic lymphatic leukemia,' since there is no fundamental pathologic difference between cases presenting low and high total white blood cell counts."* He showed records that indicated that lymphocytic leukemia may be a very benign disorder which does not materially shorten life or measurably diminish health. On the other hand, it may kill quickly. It is probable that there are many more cases in the former group than one would suspect since many are asymptomatic, do not show physical signs, and hence are not seen by the physician.

Monocytic leukemia (leukemic reticuloendotheliosis)

Monocytic leukemia is a rather rapidly fatal disease showing increased numbers of monocytes in the blood stream and in other organs. It was first reported by Reschad and Schilling[774] in 1913. Rosenthal[775] reported the first case in America in 1921. A large number of cases has since been reported, 127 in all in the American literature up to June, 1937, and many cases of this disease are on file in the Registry of Blood Diseases of the American Society of Clinical Pathologists. Osgood[776] reported 6 cases and Rosenthal and Harris and Doan and Wiseman found reports of 532 cases of leukemia, from which statistics on the incidence of monocytic leukemia were calculated. It was estimated that 62.2% of all cases of leukemia reported in the literature were cases of myelocytic leukemia, 32.7% were cases of lymphocytic leukemia, and 5.1% were cases of monocytic leukemia.

In considering this disease, the two schools of thought relating to the origin of blood cells must be taken into account. One school, of which Naegeli is a proponent, denies the reticuloendothelial source of the monocytic cells, and the other, of which Schilling is the leading proponent, insists that these cells originate from reticuloendothelial structures. It can no longer be denied that there are certain cases of monocytic leukemia which begin to all intents and purposes as myelocytic leukemia. These cases inevitably become cases of pure monocytic leukemia. Naegeli has claimed that monocytic leukemia is a temporary monocytic phase of myelocytic leukemia, and that the monocyte is a descendant of the myeloblast. He denied that monocytic leukemia is a distinct pathologic entity and cited cases which at one time exhibited the hematologic features of monocytic leukemia and in which the typical blood picture of myelocytic leukemia developed later. From such cases he claimed to trace intermediate stages between myeloblasts and monocytes. Merklen and Wolf,[777] Gittins and Hawksley, Reich, and others have reported cases supporting Naegeli's views. On the other hand, Schilling and his followers have maintained that monocytic leukemia is a distinct pathologic entity in which there is monocytosis in the circulating blood and hyperplasia of the reticular tissue in the hemopoietic organs. Schilling maintains that this disease is separate from myelocytic and lymphocytic leukemia. Forkner[765, 778, 779] believes that monocytes and their precursors are not a part of the reticuloendothelial system and that there is no clear-cut evidence of any intimate relationship between monocytes and the reticuloendothelial system, if the latter is considered in its strict sense. He likewise claims that any relationship of monocytes to myeloblasts has never been

proved, and he does not believe that the type of leukemia ever changed, for example, from monocytic to myelocytic leukemia.

It is for the reason that undoubted cases of myelocytic leukemia changing to monocytic leukemia have been reported by reliable workers that it is necessary to divide monocytic leukemic cases into 2 types: first, the monocytic leukemia of the Schilling order and, second, the monocytic leukemia of the Naegeli type.[780]

Monocytic leukemia of Schilling type

Monocytic leukemia may occur at any age, the youngest patient reported being 11 mo. old and the oldest 78 yr. of age. The clinical course runs about the same as the other acute leukemias, lasting from 2 weeks to a few months. Infection of the mouth or throat and spontaneous purpura are commonly seen. Swelling of the gums is a constant feature and is more marked and constant than in other cases of acute leukemia. This swelling is associated with gangrenous stomatitis. There is enlargement of the spleen and lymph nodes. Enlargement of the liver is also common, having been observed in 66% of the 90 cases in which a notation was made. Other clinical symptoms are pallor, weakness, and fever. There are also cutaneous lesions of 2 types: firm and painless nodules in the skin, which on histologic examination prove to consist largely of monocytes, promonocytes, monoblasts, and reticular tissue, and staphylococcic infection of the skin, with multiple boils and carbuncles.

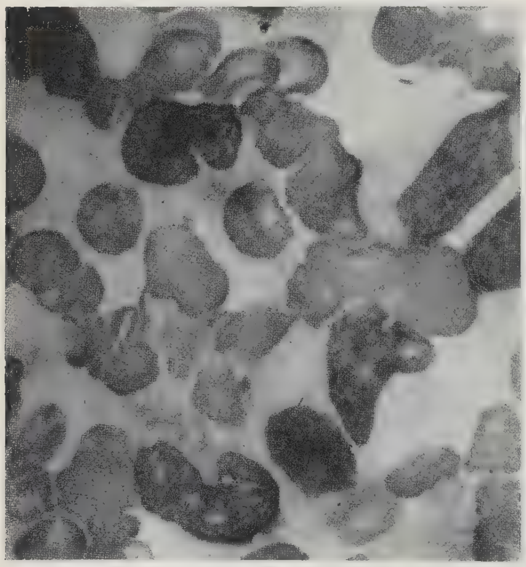

Fig. 447. Endocarditis, blood film, showing endothelioid monocytes. (×950.)

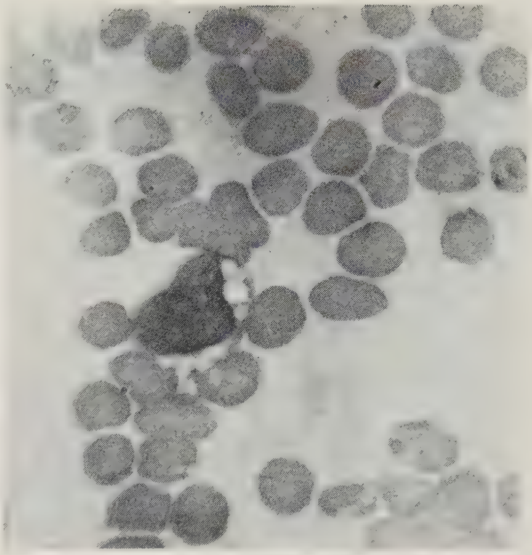

Fig. 448. Blood film showing a phagocyte. (×950.)

Blood picture: The blood picture shows a marked or moderate decrease in red cells and hemoglobin. There is a definite increase in the white cell count. The average of the highest counts recorded in each case was 99,600. A few cases showed leukopenia. Differential count showed mature monocytic cells forming about 50-75% of the total count. Sometimes immediate precursors of the monocyte, including the histiocytes, are present. The cytoplasm resembles that of the mature monocyte, being of blue-gray color and of ground-glass appearance, with typical fine monocytic granules which are first seen about the nucleus in the youngest cells. The nucleus is large, oval, bean-shaped, or even lobulated. The chromatin is arranged in a very fine spongelike meshwork which becomes coarser and skeinlike in more mature cells. Although most of the observers report that the immature cells are oxydase-negative, Farley[781] and Lawrence[782] and co-workers found the cells to be oxydase-positive.

Histologically, the architecture of the lymph nodes and spleen is obliterated by a marked proliferation of reticular cells. Periportal growth is seen in the liver, and proliferation of reticular cells is found in the kidneys, the serosal surfaces, and the perivascular stroma of nearly all the organs, especially the adrenal glands, thymus, pancreas, and gastrointestinal tract.

The **bone marrow** shows a preponderance of monocytic cells. These are monoblasts which are very large, from 15-30μ in diameter. Chromatin structure of the nucleus is very fine, similar to that of the myeloblast but even more transparent. The nucleus is usually round or oval. The cytoplasm ranges from basophilic to deeply basophilic, and there is more in proportion to the size of the nucleus than in the myeloblast or the lymphoblast.

As Osgood pointed out, monoblasts are difficult, sometimes impossible, to distinguish from myeloblasts or lymphoblasts. The chief difference is the more frequent occurrence of fine, diffuse azurophil granules in the cytoplasm of the monoblast, similar to those of the mature monocyte. Peroxidase stain does not assist in this differentiation, as all these cells may show a negative peroxidase reaction. From his study of 6 cases and a review of the literature, Osgood definitely believes that the monocyte is developed from a cell which may be called the monoblast, similar in morphology to the myeloblast. This is very interesting in view of the fact that Forkner has listed 19 different views as to the origin of the monocyte, which clearly shows the confusion that exists in regard to the origin of this cell. It is gratifying to know that a hematologist of Osgood's experience has so definitely accepted the entity of the monocyte as so determinedly maintained by Schilling and his followers all these years.

Monoblasts frequently contain Auer bodies.

Monocytic leukemia of Naegeli type

A report by Hall and Watkins[783] may be taken as an example of the monocytic leukemia of the Naegeli type, i.e., beginning as myelocytic leukemia and changing to monocytic leukemia. Hall and Watkins believe that a "monocytic phase" may develop at any time in the course of myelocytic leukemia or that the picture may be that of monocytic leukemia when the patient is first seen, later changing to one of chronic myelocytic leukemia which at a later date changes to one of monocytic leukemia, as was demonstrated by the case reported. Levine[784] reported a case which was studied for a long time because of severe anemia of indeterminate type. Ten days before death, a leukemic blood picture developed in which myeloid immaturity toward the stem cell and mature and young monocytes were observed, with the findings at necropsy of subacute myelocytic leukemia. Levine expressed the opinion that this picture illustrated the development of a monocytic phase in the course of myelocytic leukemia after an initial aleukemic phase.

Hall and Watkins studied all of the cases of monocytic leukemia seen at the Mayo Clinic in a 10-year period and found that 23 cases were of the Naegeli type and 6 were of the Schilling type. They believe that the Naegeli type of monocytic leukemia should be considered a variant of myelocytic leukemia and the Schilling type a variant of leukemic reticuloendotheliosis.

There have been a number of erroneous conclusions about monocytic leukemia due to the fact that only single observations have been made on some cases. Thus at various times the features of agranulocytosis, aleukemic myeloid leukemia, aplastic anemia, leukemoid monocytosis, leukopenic infectious monocytosis, chronic splenic panhematopenia, and reticuloendotheliosis have been depicted. Monocytic leukemia may pursue a very erratic course. This was exemplified in the unusual case reported by Rappoport and Kugel.[785] This case was exhaustively studied. There were 4 sternal punctures. There were several episodes of granulocytopenia. Serial blood counts were made, and autopsy findings were very complete in this case. The conclusion was drawn that this was unquestionably a case of true monocytic leukemia. The authors believe that the distinction between the Schilling and Naegeli types of monocytic leukemia is more apparent than real and does not deserve the rigid segregation frequently employed and heretofore alluded to in this chapter. A similar contention has been advanced by Campbell et al.[786] and Custer.[787] This case illustrated, as do most of the cases, that in the later stages of the disease as the frank monocytic leukemia progresses the myeloid reaction diminishes. This myeloid reaction is for the most part an expression of the bone marrow reactivity to the agranulocytosis and is not an expression of the monocytic leukemia.

There are certain essential facts which must be borne in mind relative to the diagnosis of this disease. One of these facts is the proper identification of the monocyte. It is usually larger than the granulocyte; its cytoplasm is opaque and mottled, has a gray-blue color, and contains azurophilic granules. The cell margins are serrated and irregular. The nucleus is reniform or horseshoe-shaped and possesses a lacy, skeinlike, coarse chromatin weave. With supravital stain numerous neutral red or salmon-pink colored bodies, vacuoles, are symmetrically arranged around a centrosphere located in the bay of the nucleus. This structure is the rosette which is considered so typ-

ical of the mature monocyte. Moreover the monoblast measures from 15-20μ in diameter, and in fixed stained films it possesses a basophilic cytoplasm containing no granules and, distinctively, no Auer bodies. The nucleus is round, large, and centrally situated; its chromatin is fine, stippled, and sievelike and usually possesses two nucleoli.

Rappoport and Kugel emphasize that this diagnosis requires prolonged and intensive clinical and laboratory observations.

Lymphocytic leukemia following benzol poisoning

Falconer[788] reported a case of chronic benzol poisoning, gradually developing the picture of a typical leukemia as follows.

> The patient, a man 58 yr. of age, was employed in a can factory. The can ends, rimmed with a solution of rubber in benzol, were delivered to him by a conveyor, the benzol evaporating from the rubber mixture en route. Falconer had seen 4 cases of typical benzol poisoning from the same plant during the previous year. This patient's blood studies showed 50% hemoglobin, 1,530,000 red blood cells, 8100 white blood cells, 62% neutrophils, 32% lymphocytes and 6% monocytes. Blood platelets numbered 68,000; red cells showed anisocytosis and some polychromasia. The symptoms were diagnosed as chronic benzol poisoning. Later on hemorrhages from the nose began, together with decrease in red and white counts. After a blood transfusion, the nasal bleeding ceased. About a month later the patient returned for treatment, and 2 mo. later the bleeding from the nose reappeared. The blood picture showed decrease in the number of red cells and amount of hemoglobin, but the white cell volume rose. About 4 mo. later, he showed a picture of beginning lymphocytic leukemia, the counts running up to 50,000. This state persisted for about a year when death occurred, with a clinical diagnosis of lymphocytic leukemia.

Three important questions were suggested by a study of the clinical data and autopsy material on this patient. The autopsy material, by the way, showed general lymphadenopathy, increase in size of the spleen, leukemic infiltration of the liver and kidneys, secondary anemia, bronchopneumonia, and purulent bronchitis. The lymph nodes showed a striking overgrowth of tissue by a type of cell which was larger than the usual lymphocyte and which contained a thin rim of cytoplasm. The bone marrow showed the same type of cell as the lymph node.

The questions are as follows:

1. What effect does benzol have on lymphatic tissue?
2. Is it not possible for benzol, like other well-known hemopoietic irritants, to upset the hemopoietic balance between cell growth and destruction, giving rise to lymphoid hyperplasia?
3. Does this lymphoid hyperplasia always stop just short of leukemia, or can it under prolonged irritation or in susceptible individuals progress to lymphocytic leukemia?

Lignac[789] injected mice with from 25-30 injections of benzol (0.1 ml. of a solution of 0.3 ml. benzol in 10 ml. olive oil) and concluded that the symptoms of hyperplasia developed and that the spleen, which was first hypertrophied, decreased in size. The animals showed hyperplasia but no lymphocytic leukemia. He did not succeed in producing lymphocytic leukemia. The hyperplasia he considered a tumorous growth similar to leukemia. It is a real tumor of precursors of white blood cells. He stated that the immaturity of undifferentiated cells suggests acute leukemia, and the development of a tumor may or may not be accompanied by a leukemic blood picture.

Murphy and Sturm[790] reported experimental work with hemopoietic irritants accomplished by subjecting mice, rats, and guinea pigs to dry heat at temperatures of from 55°-65° C. with short exposures of about 5 min. White cell counts were made at intervals over a 3 wk. period. The blood picture showed an immediate drop in both neutrophils and lymphocytes, which averaged about 3000 cells/c.mm. Seven days after the heating there was an increase of from 5000-10,000 cells/c.mm., the increase being almost entirely in the lymphocytes. Fourteen days after heating, the lymphocytes had increased to from 12,000-14,000/c.mm. above the original counts; the neutrophil count remained low and did not increase until about 3 wk. after heating. From 6-10 days after heating several lymphocytes were noted apparently in the process of amitotic division. These cells in the process of division looked very much like the cells reported by Falconer in his case of leukemia following benzol poisoning.

Nakahara,[791] in trying to determine the source of lymphocytosis induced by heat, found the first change in the spleen and the lymph glands with widespread degeneration of the lymphoid elements. This was followed in 48 hr. by activity of the germinal centers, with an overproduction of lymphocytes, the spleen and lymph glands becoming larger than normal. There was a marked increase of mitotic figures in the lymphocytes of the germinal centers following the general necrosis.

Benzol presumably may act on lymphatic tissue in a manner similar to dry heat, causing destruction first then a compensatory hyperplasia exceeding the normal limits. It is questionable whether this might not later result in leukemia.

Experimental work carried on at the Rockefeller Institute[792, 793] shows that with a certain dose of roentgen rays lymphocytosis similar to that produced by heat can be brought about, i.e., first a lymphocyte fall, followed by a marked rise.

Basophilic leukemia

There is some dispute as to whether or not there is actually an entity which may properly be called basophilic leukemia. Many contend that these are cases of chronic myelocytic leukemia with large numbers of basophils. Groat and others[794] reported a case of acute basophilic leukemia which seems to bear out their belief that this entity may actually occur. They cite the report of Joachim[795] who in 1906 reported 2 cases of chronic leukemia in both of which the percentage of mast cells or basophilic cells was above 50. The blood picture in Joachim's case was of an ordinary chronic myelocytic leukemia except for the large number of mast cells, as high as 83%. Joachim's opinion was that the general symptoms were similar to other chronic myelocytic leukemias except for the degree of basophil increase. He reported it as a case of atypical leukemia, concluding that chronic basophilic leukemia is a variety of the common myelocytic variety. Sabrazès[796] in reporting a case of chronic myelocytic leukemia with many mast cells stated that the so-called hemohistioblast of Ferrata and many types of basophils were frequently found increased in chronic myelocytic leukemia. Elliott and Young[797] reported a case of chronic mast cell leukemia because of a predominance of leukocytes with coarse basophilic granulation.

Casey et al.[798] discussed what has already been stated in this book, namely, whether there is a true basophilic leukemia distinguishable from the neutrophilic type. Doan and Reinhart[799] reported 3 cases which they believed to be true basophilic leukemia. They seemed to believe that these were the first instances of this sort to be reported.

The case reported by Casey et al., which records the sixth case in the literature with clinical observations for at least 1 month before death, emphasized that there is no evidence at present that basophilic leukemia ever occurs except as a terminal phase of neutrophilic leukemia. They made a very proper recommendation for future observers, namely, that only those cases should be reported as basophilic leukemia in which (1) blood studies using supravital and peroxidase stains, together with routine blood examinations, have been made, (2) hematologic observations on the patient have been available for more than 3 months prior to death, and (3) postmortem examination with supravital studies of spreads from the bone marrow, blood, spleen, lymph nodes and alcohol fixation of the tissues for the preservation of the water-soluble basophilic granules have been made.

The relationship of blood basophils to the tissue mast cells and their functions has been considered in the discussion of basophils and mast cells. Cases of mast cell leukemia have been reported as well as several cases of urticaria pigmentosa associated with systemic involvement (mastocytosis).

Eosinophilic leukemia

Eosinophilic leukemia represents a rare form of chronic myelogenous leukemia and must be carefully separated from the more common eosinophilic leukemoid reaction. In order to establish the diagnosis of eosinophilic leukemia the peripheral smear must contain such immature cells as eosinophilic myelocytes and promyelocytes and myeloblasts. The finding of Auer bodies, Rieder cells, and anisocytosis (giant forms) of the eosinophilic granulocytes is very helpful. Leukemic eosinophils frequently exhibit irregular granulation since all the granules may not stain with acid dyes but accept basic dyes, thus masquerading as basophilic granules.

Plasma cell leukemia

In the literature there have been 62 cases of plasma cell leukemia reported. Foa[800] reported the first case. He called it pseudoleukemia plasmacellularis. He found plasma cells in the blood and diffuse infiltration of the bone marrow, liver, spleen, and some lymph nodes. Moss and Ackerman[801] reported a case in September, 1946. This man showed symptoms of swelling of the lower jaw, bleeding gums, and enlargement of the spleen and liver. The blood picture showed 13,700 leukocytes, with a differential count of 4% myelocytes, 14% juvenile cells, 15% stab cells, 24% segmented neutrophils, 23% lymphocytes, 6% monocytes, 2% eosinophils, and 1% basophils, with 11% plasmacytes, 4 pronormoblasts, and 24 normoblasts. The sternal bone marrow showed the marrow completely replaced by plasma cells. Diagnosis of plasma cell leukemia was made. Plasma cells reached a maximum value of 22%. There was a hyperglobulinemia throughout the disease. Autopsy 1½ months after admission to the hospital showed splenic enlargement, liver enlargement, and microscopically plasma cells present in every region of the liver. Spleen sinuses were plugged with plasma cells. Lymph nodes showed invasion of plasma cells, likewise the pancreas. Bone marrow showed a complete replacement of normal elements by a diffuse infiltration of plasma cells.[1]

Plasma cell leukemia represents the leukemic phase of multiple myeloma, a disease which can be considered to be a subleukemic or aleukemic leukemia. Its leukemic phase is rather uncommon.

In reference to clinical findings in this disease, it is usually found between the ages of 45 and 60 yr. The symptoms of plasma cell leukemia in the majority of cases are those of multiple myeloma. Pain in the arm, back, legs, or substernal region may be present, with a history of lassitude, weakness, and weight loss. There is a tendency to hemorrhage. Bleeding is nearly always from the gums and nose. The bone destructive nature of plasma cell leukemia is exemplified by frequent pathologic fractures. In the bone marrow there is diffuse infiltration with plasma cells. These cells do not differ from those in the blood, except that in the blood the plasma cells tend to be smaller. The liver is invaded by plasma cells and likewise the spleen and lymph nodes.

It should be stressed that, although we generally call these cells plasma cells, the term myeloma cells is distinctly preferable. In multiple myeloma and plasmacytic leukemia the proliferating cells are rarely mature plasma cells but usually differ from the mature forms by their large size, their variability in size, their variably stained cytoplasm (from deep blue to light blue and pink), their larger nuclei, the absence of perinuclear clear zones, their multinucleation, and the frequent presence of prominent nucleoli. The plasma cells found in the blood are usually much more mature than the ones infiltrating the bone marrow.

Askanazy[802] formulated the following requirements for a diagnosis of plasma cell leukemia:

1. Plasma cells must be present in the peripheral blood.
2. Leukocytosis must be present.
3. The bone marrow must be diffusely involved.

A bone marrow biopsy showing diffuse plasma cell infiltration, together with finding the typical cells in the circulating blood, is necessary and usually sufficient.

Bone marrow infiltration by plasma cells unaccompanied by more than occasional plasma cells in the circulating blood may be found in hepatic cirrhosis, agranulocytosis, miliary tuberculosis, carcinomatosis, collagen diseases, allergies, and aplastic anemia. As stated in the discussion of plasma cells, there are a number of blood diseases characterized by transition forms of plasma cells and lymphocytes—lymphoid plasma cells—as seen in Waldenström's macroglobulinemia and in some cases of chronic lymphatic leukemia.

Laboratory findings: In plasma cell leukemia the leukocyte count is usually 10,000-40,000. The percentage of plasma cells found in the peripheral blood varies from 87-1%. The erythrocyte count is low. Anemia follows the same pattern as in other leukemias. There is a low blood platelet count which is reflected in the high percentage of hemorrhagic tendencies. Just as in multiple myeloma, hyperglobulinemia and dysproteinemia are sometimes present in plasma cell leukemia.

Bence Jones bodies: The test for Bence Jones bodies in the urine was performed in 20 of 37 cases of plasma cell leukemia. Six of these were positive, and the rest were negative. A positive test is good evidence of multiple myeloma, for it is infrequent that Bence Jones bodies are found in diseases other than multiple myeloma.

Megakaryocytic leukemia (platelet leukemia)[803, 804]

This is an interesting condition which belongs to the myeloproliferative disorders and which may not be a disease entity *sui generis* but rather a form of myelogenous leukemia, myelofibrosis, or erythroleukemia. The disease probably begins asymptomatically in the early years of life and leads to splenomegaly but is not acompanied by leukemic manifestations. After surgical removal of the spleen, usually because of the discomfort produced by its large size, the blood picture rapidly assumes leukemic characteristics, and evidence of myeloid metaplasia appears in the liver and lymph nodes. Clinically, despite the marked increase in platelets and megakaryocytes, the patient shows bleeding tendencies. The spleen

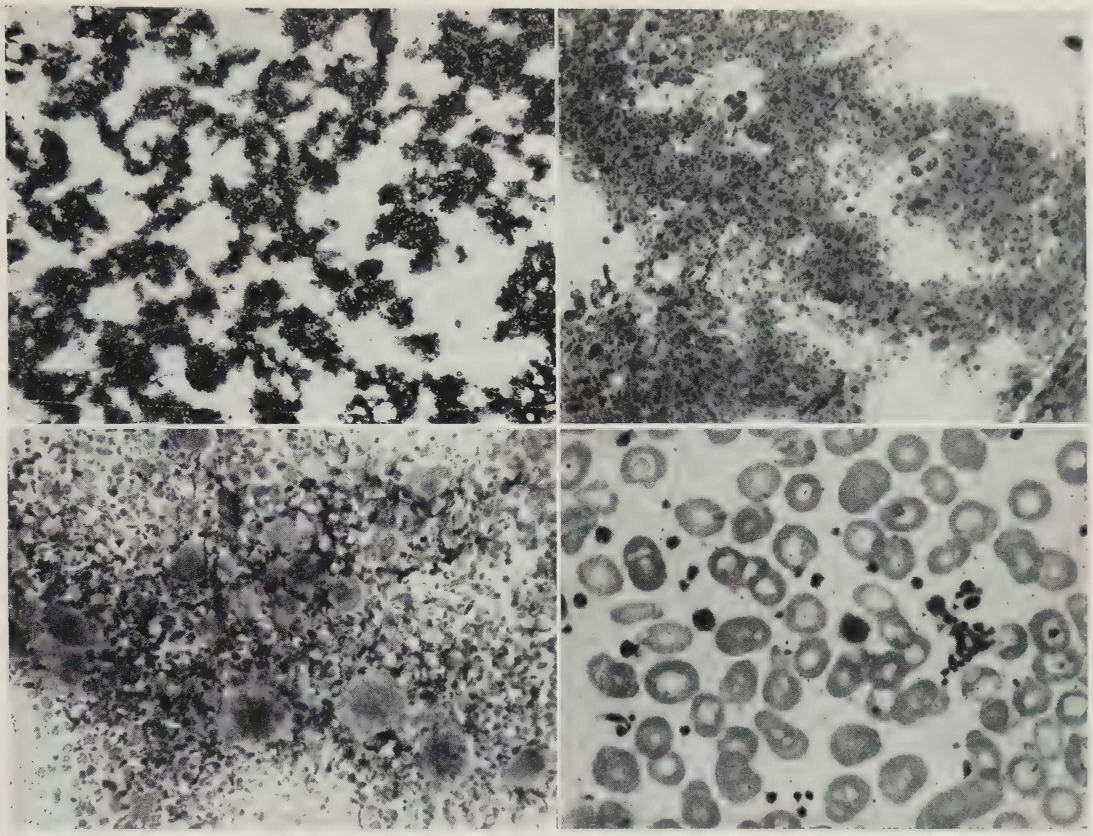

Fig. 450. Megakaryocytic leukemia; bone marrow completely replaced by masses of platelets or by masses of megakaryocytes. Peripheral blood; increased number of abnormal platelets.

appears to be vitally involved in this disease process. Review of the literature shows that not all cases follow the pattern just outlined, but all are preceded by either physiologic removal (fibrosis, calcification, or congenital absence) or surgical removal of the spleen. It thus seems that the loss of the spleen also entails the loss of a bone marrow-inhibiting factor, allowing unrestricted bone marrow proliferation.

Aleukemia, subleukemia, or leukemia without leukocytosis

This disease is so called because of its histologic and pathologic-anatomic symptoms. There are anemia, enlarged glands, and splenic tumor. These cases may show a leukemic blood picture with almost a **normal total count.** Aleukemic conditions may be temporary or may change into manifest leukemia. Pinkus believes that the lymphocytic aleukemia is the most common variety. The blood picture rarely approaches normal. There is relative and sometimes absolute lymphocytosis, with normal or high normal counts. According to Schilling there is a high-grade regenerative shift. There are 60% lymphocytes, with occasional lymphoblasts. These cases are characterized by lymphoblasts, atypical lymphocytes, and Rieder forms with lobulated nuclei, in conjunction with signs of a severe anemia.

Many authoritative sources have reported cases of leukemia without leukocytosis and without enlargement of the spleen. Hirschfeld,[805] for instance, reported 4 cases of leukemia without splenomegaly. Ordway and Gorham[806] reported 1 case, and Kracke and Garver[807] also described 1 case. Weber[808] reported 1 case of aleukemic myelosis without splenic enlargement in which the condition clinically simulated aplastic anemia. He believes that many cases in which the clinical diagnosis was aplastic anemia were undoubtedly examples of aleukemic myelosis. In other words, we can now speak of the condition called **aleukemic myelosis,** which is leukemia without leukocytosis and without enlargement of the spleen. Mettier and Purviance[809] reported 5 cases of leukemia in patients who had no leukocytosis and no splenic enlargements. The clinical findings were those of severe anemia, thrombopenia, and leukopenia with the presence of immature forms of leukocytes in the stained films of blood.

The first case showed 7600 leukocytes/c.mm., with a differential count of 39% segmented cells, 2% nonsegmented cells, 45% lymphocytes, 3% monocytes, 4% myelocytes, 5% myeloblasts, and 2% unclassified immature forms. One nucleated red blood cell was seen per 100 white blood cells. There was diminution in the number of blood platelets.

The patient presented the clinical symptoms of a severe blood dyscrasia and died following hemorrhage from the bladder and gastrointestinal tract. The clinical diagnosis was aleukemic myelosis, with slight leukemic metaplasia of the cervical lymph nodes. Section of this cervical lymph node showed that the architecture of the lymph node had been largely replaced by tumor cells of various sizes, mostly of the myeloid type. There were myelocytic cells of the neutrophilic and eosinophilic types present.

A second case was a 38 yr. old white man who showed 2300 leukocytes or very definite leukopenia, with a differential count of 7% polymorphonuclear cells, 22% nonsegmented neutrophils, 42% lymphocytes, 26% monocytes, 1% myelocytes, and 2% unclassified cells. Two nucleated red blood cells were seen per 100 leukocytes in the stained film. Blood platelets were found greatly reduced. This patient showed anemia and leukopenia, with no apparent hematopoietic reaction to liver extract given either parenterally or by mouth. After a number of weeks the patient returned to the hospital, from which he had been discharged, with the same picture with 20% myelocytes, and 16% myeloblasts, and 40,000 platelets/c.mm. Clinical diagnosis was aleukemic myelosis with anemia and thrombopenia.

There were several other cases reported of similar type.

It is interesting to note that the biopsy of the **bone marrow** from the sternum afforded a valuable aid in establishing the diagnosis. Specimens of the marrow showed a predominance of undifferentiated types of cells, many of which contained mitotic figures packed solidly together to the exclusion of fat cells. This picture of the bone marrow indicated hyperplasia which was undoubtedly leukemic.

DISEASES SIMULATING LEUKEMIA

Lymphosarcoma

Lymphosarcoma is a malignant tumor composed of lymphocytes and lymphoblasts. Hematologically lymphosarcoma may show no detectable changes in the peripheral blood except perhaps a secondary anemia or occasional low-grade lymphocytosis or both. The neoplastic cells may break over into the blood stream in greater or lesser number, producing a type of leukemia first described by Sternberg[810] as leukosarcoma. Wiseman records the results of a series of blood examinations made in a case of lymphosarcoma in which the tumor type of cell (in contrast to normal lymphocytes) was found in the blood stream only intermittently. This case histologically answered the description of the tissue described by Brill et al.[811] under the term follicular lymphoblastoma and is the most chronic type of leukosarcoma encountered.

Chloroleukemia

The term is of historic interest only. Chloroleukemia is a disease described by Naegeli. It displays an acute leukemic blood picture. The symptoms are cachexia, severe anemia, and subperiosteal circumscribed proliferations, manifested principally on the skull. In children it is usually due to an acute myelogenous leukemia.

Leukosarcoma

Leukosarcoma was classified by Sternberg as a separate entity. These cases show the picture of acute leukemia of the lymphocytic type associated with lymphosarcoma (see foregoing discussion of lymphosarcoma).

Pseudoleukemia

The term pseudoleukemia should be discarded. It is of historic importance only and at one time described any disease exhibiting hepatosplenomegaly without a concomitant leukemic blood picture.

Hodgkin's disease

Hodgkin's disease is a malignant tumor of the reticulum cells and lymphocytes. It is of clinical importance in the differential diagnosis of leukemia but has no characteristic blood picture. The peripheral blood may reflect bone marrow involvement (myelophthisic anemia) and hypersplenic activity (hemolytic anemia) and may according to isolated reports very rarely contain Reed-Sternberg cells.

The disease was described by Hodgkin in 1832 in a publication entitled *On some morbid appearances of the absorbent glands and spleen.*[812] Many observations have been made since that time. Considerable experimental work has been done, but the etiologic agent has not yet been discovered. This disease was once called pseudoleukemia. Bonfils in 1856 spoke of it as a cachexia without leukemic changes. Virchow in 1865 classified it with the lymphosarcomata. Cohnheim, unfortunately, introduced the term pseudoleukemia, but this has been proved to be manifestly an incorrect classification. Billroth in 1869 called it malignant lymphoma; Langhans in 1872, malignant lymphosarcoma; Schulz in 1874, reticulated desmoid carcinoma; Orth in 1887, malignant aleukemic lymphadenoma; Langebeck termed it gland sarcoma.

Blood picture: The hematologic picture of this disease has been a subject that has been much discussed. **Certain it is at this time that there is no characteristic picture in the blood by which one can identify the disease as Hodgkin's disease.** There are changes, it is true, but they are not characteristic. The red cells are reduced in number, and there is usually a diminution in the percentage of hemoglobin. The red cell count may vary from 2,000,000-4,000,000 but sometimes drops to the million mark. The red cells are pale, and there are often many microcytes. Occasionally nucleated red cells are seen, together with poikilocytosis, polychromasia, and basophilic punctation. The number of white cells varies. Occasionally Hodgkin's disease displays an unusual increase in the number of white cells, but this increase is not a characteristic phenomenon. There may be leukocytosis as well as leukopenia. McAlpin[813] found the cell count ranged in 18 cases between 2000 and 13,000.

Ziegler[814] in 70 cases found the following: in 22, counts of from 5500-10,000; in 20, from 10,000-20,000; in 8, from 20,000-30,000; in 2, more than 30,000; and in 18, a leukopenia of from 2000-5500. In a general way, there is usually in the early stages of the disease a slightly increased total count or perhaps a normal count.

The differential count has been much discussed, but as yet no one has had the temerity even to suggest that there is any possibility of making a diagnosis of Hodgkin's disease from the differential count. Early in the disease there may be lymphocytosis, but this is not positive. Leukopenia with relative lymphocytosis has been described in the beginning of the disease. Much emphasis has been laid upon the **eosinophilia** in Hodgkin's disease, but this has been denied by others. **The eosinophilia, if present, is of diagnostic importance, but if absent, is not sufficient to exclude this disease.**

The actual diagnosis of Hodgkin's disease can be made only by excision of one of the lymph nodes and histopathologic study.

Nonhematologic findings: In common with the tumors of lymphatic tissue, Hodgkin's disease shows abnormalities of the serum protein characterized by an increase in the alpha globulins and in the component containing ceruloplasmin, whereas albumin and the siderophilin-containing component are decreased.[815]

BRILL-SYMMERS DISEASE (GIANT FOLLICULAR LYMPHOBLASTOMA)

Brill-Symmers disease involves the lymph nodes and the spleen. The lesion is essentially a neoplasm of the reticulum cells. Its importance lies in the fact that it must be considered in the clinical differential diagnosis of the leukemias. The blood picture is not diagnostic.

Clinical symptoms: Lymph nodes become enlarged, remaining discrete, and may become as large as 10 cm. There are usually weakness, anorexia, loss in weight, and low-grade fever.

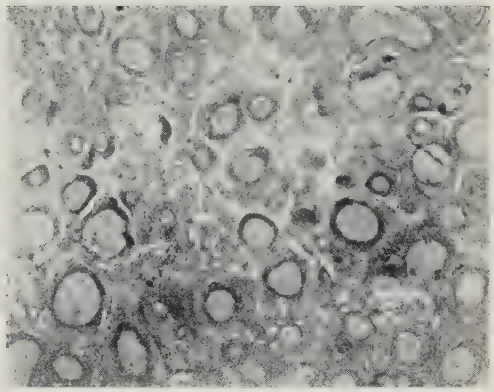

Fig. 451. Benign type of multiple giant follicular lymphoblastoma. (Courtesy Dr. Walter Siebert, St. St. Louis, Mo.)

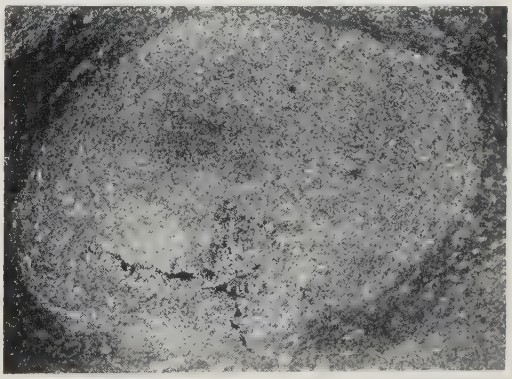

Fig. 452. High-power enlargement of lymphoblastoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

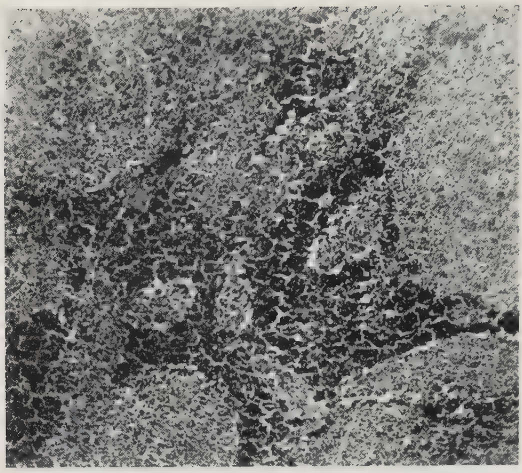

Fig. 453. Low-power view of early transformation of giant follicular blastoma into polymorphous cell lymphosarcoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

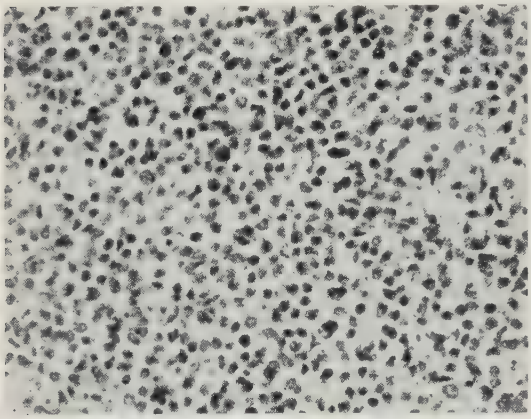

Fig. 454. High-power view of polymorphous cell lymphosarcoma arising from a giant follicular blastoma. (Courtesy Dr. Walter Siebert, St. Louis, Mo.)

Blood picture: Ten per cent of the cases show mild leukopenia, with lymphocytosis of from 50-60%, and mild eosinophilia of 4-6%. There may be a slight anemia and occasionally thrombocytopenia, probably of hypersplenic origin. The bone marrow is usually not involved.

The disease is important because it is likely to be confused with other conditions. Biopsy of the glands should be sufficient to clarify the situation.

LYMPHADENOPATHY

One may divide all lymphadenopathies into 2 classifications: (1) those in which the predominant characteristics are significant of malignancy and (2) those in which the reaction is like an infectious process.

The first classification is composed of 3 clinical subdivisions: (1) lymphosarcoma, including those tissues having the pathology typical of lymphosarcoma, lymphoblastoma, reticulum cell sarcoma, or plasmacytoma, (2) the leukosarcomas and the aleukemias as well as the pure myelocytic, lymphocytic, or monocytic leukemias, and (3) true tumor metastases.

The second major classification, the infectious nonmalignant lymphadenopathies, comprise 4 clinical types: (1) lymphatic tuberculosis, (2) syphilis, (3) simple lymphadenitis (infections of focal origin), and (4) infectious mononucleosis.

Differential diagnosis: At this point the knowledge of the regional anatomy of the lymphatic tissues is indispensable in differential diagnosis; for instance, enlargement of the preauricular node may be due to a focus of chronic conjunctivitis. In order to make a correct diagnosis one must consider the following points: temperature, characteristics of the nodes, splenomegaly, blood picture, and biopsy.

Fever is found only among the diseases of the infectious group.

With respect to the characteristics of the nodes, the presence or absence of pain, the distribution of the swellings, whether local or generalized, and third, the physical characteristics imparted to the palpating fingers by the diseased nodes are points to be determined. Painful glands suggest infection which may be inflammatory.

Distribution of the gland swellings is important. Thus generalized adenopathy without fever is characteristic of the chronic leukemias, the afebrile stage of Hodgkin's disease, and the benign hypertrophies; if fever is present, a generalized swelling means syphilis, Hodgkin's disease, infectious mononucleosis, generalized lymphatic tuberculosis, serum sickness, or an acute phase of leukemia. Local swelling without fever suggests lymphosarcoma, tumor metastasis, lymphadenosis, tertiary syphilis, or Hodgkin's disease. Local swelling combined with pain and inflammation is nearly always indicative of local infection, either lymphatic tuberculosis or pyogenic lymphadenitis, but never of Hodgkin's disease.

Palpation gives important data. Some cases of metastatic carcinoma and some very chronic types of Hodgkin's disease show very hard and unyielding glands, but many do not. Many malignant adenopathies and cases of Hodgkin's disease exhibit discrete not fused glands. In leukemia the glands are always discrete and elastic to the touch. A chronic fluctuant or soft node if painful, adherent to the skin, or showing evidence of previous sinus infection usually means localized lymphocytic tuberculosis.

So far as enlargement of the spleen is concerned, a hard spleen extending nearly to the umbilicus with concomitant generalized adenopathy nearly always means leukemia—and the larger the spleen the more likely is the leukemia to be myelocytic in type. In Hodgkin's disease the spleen does not usually extend much below the costal border and is not palpable at all in one-half of the cases. A slightly enlarged spleen is seen in infectious mononucleosis.

Blood picture: In malignant cervical adenopathies the blood picture is normal except in those patients in an advanced stage or with leukemia. Leukocytosis with neutrophilia is strong evidence that the adenopathy in question is of infectious origin. With lymphocytosis, mononcytosis, and mild anemia of the hemoglobin type, we suspect lymphatic tuberculosis; with lymphopenia, eosinophilia, and monocytosis, and usually leukopenia, with marked anemia of the red blood cell type, the blood reflects Hodgkin's disease. Normal total red and white cell counts, with eosinophilia and lymphocytosis suggest syphilis; marked lymphocytosis and normal red cells suggest infectious mononucleosis.

Biopsy: Select the gland that is most likely to contain the most pathology; i.e., usually the largest gland. Remove the entire tissue but do not cut across or rupture the gland.

TREATMENT OF LEUKEMIA AND MALIGNANT LYMPHOMAS

There is as yet no satisfactory treatment of leukemia or malignant lymphomas, but interest is great as the tremendous amount of basic research and animal experimentation in this field bear witness. Despite the generally poor results in treatment, advances have been made that suggest the possibility of success in the future. Perhaps the most outstanding feature of present-day therapy is the attack on these diseases with the use of chemotherapeutic agents based on some new concepts.[816] Basically this concept is that the cancer cell (leukemic or otherwise) can be regarded in principle much like invading microorganisms. These latter can be destroyed by chemotherapeutic agents while in the human host. Then why not attempt to destroy cancer cells in the same way without injuring normal cells? The basic principles of this approach are (1) the principle of dynamic equilibrium and (2) that of specific nutrition. Principle 1 states fundamentally that all cells require a constant supply of proper nutriments to survive. Principle 2 states that different cell types may have different nutritional requirements either from their external environment or within their internal mechanism. This concept has been referred to as the heterogeneity of nucleic acid anabolism. The researches of the Sloan-Kettering group have been directed at applying these concepts by selective feeding of modified chemical agents to cancer cells effecting a starvation of the cell particularly directed at nucleic acid metabolism. These investigators have repeated in tissue culture of normal and cancer cells what can be shown in bacterial cultures, namely, selective destruction of cells by chemical agents.

SubbaRow's[817] synthesis of folic acid (pteroylglutamic acid) and the finding that the clinical course of acute leukemia was unfavorably affected by this substance or its conjugates led Farber and associates[818] to use folic acid antagonists in the treatment of acute leukemia in children. The Sloan-Kettering investigators have carried on extensive animal research with these chemical compounds, as well as with others, with very promising results. Using 10 different compounds on 5- to 7-day-old tumors in mice, 1275 animals (67%) out of 1910 treated were cured. In mouse leukemia, 44% cures were effected with 6 selected compounds. Amethopterine, an analogue of Aminopterin, was found 98% effective against Line I mouse leukemia but effected no cures in Line I/A, a resistant strain. However, when a combination of P-165 (azaserine or 0-diazoacetyl-L serine) and 6-MP (6-mercaptopurine)* was used against this resistant Line I/A strain, 98% of the mice were cured of leukemia. These results are most encouraging in that an approach appears possible that may shed a ray of hope in the treatment of human leukemias.

To date no human cures of leukemia by chemical or other agents have been effected. The literature on the use of these agents is voluminous and has been excellently reviewed by Wright et al.[819] Therapy with the folic acid antagonists has been the subject of a lengthy supplement of *Blood*.[820] Chemotherapy of leukemia, Hodgkin's disease, and related diseases based on 10 years' experience has been reported by Wintrobe et al.[821] The folic acid antagonists which have been used in the treatment of leukemia are Aminopterin, Amethopterin, Amino-an-fol, Adenopterin, and Aminoteropterin. All of these related compounds are pteroylglutamic or pteroylaspartic acid derivatives. Farber's enthusiasm for the results achieved with these antagonists has not been shared by everyone, and results from their use have varied. Whatever else may be said about these compounds, one thing stands out in our minds: hopeful events have happened in patients with acute leukemia that never happened before these agents came along. Everyone who has treated acute leukemia, especially in children, agrees that the folic acid antagonists have a profound effect on this disease, which in the past left us dismayed and hopeless as it ran its speedy course unchanged by any known form of therapy. The most striking cases are those in which the peripheral blood picture may approach normal and in which the bone marrow shows considerably diminished leukemic activity. It is claimed that in some rare cases autopsy failed to show any evidence of leukemia. Clinically these patients display improved vigor, require fewer transfusions, and are generally useful. These remissions may last only a few days up to many months.

---

*Purinethol; Burroughs Wellcome & Co., Tuckahoe, N. Y.

When one tries to analyze statistics as to the benefits derived from folic acid antagonist therapy, there are many variables that readily account for the differences in opinion. Cases of acute leukemia are fortunately relatively rare, and very few observers have had an opportunity to manage sufficiently large enough numbers of patients to make their statistics entirely acceptable. The classification of acute leukemias may vary from one group of investigators to another, which adds another variable to statistical analyses. As with all investigations and therapeutic approaches to disease, the intensity of interest and enthusiasm of the investigator is often reflected in beneficial results in patients not achieved by physicians whose interest is more casual. This involves not only more careful dosage schedules but also care in general management that adds some imponderables to successful therapy.

With folic acid antagonist therapy there is no unanimity of opinion as to whether treatment should be pushed to toxicity with high dosage and a rest period or whether modest dosage schedules should be followed intermittently, or if there should be continuous therapy. Whatever schedule is followed, leukocyte counts and the blood picture are generally helpful and necessary in following these cases. In some cases the white cell count may return to normal or nearly normal values, with disappearance or diminution of leukemic cells in the blood film.

One of the troublesome problems in many of these patients is that leukopenia is a common accompaniment of the natural history of acute leukemia and that the blood films may show relatively few leukemic cells. Studies of the bone marrow in such cases show a wildly active leukemic process. Should these patients be given a leukopenia-producing agent? If so, what should determine dosage? Situations such as these appear to require more courage than scientific knowledge. When toxicity occurs, the symptoms may be more distressing than those related to the leukemia: affection of the gastrointestinal tract, with gingivitis, stomatitis, anorexia, and bloody diarrhea. Folic acid and citrovorum factor, vitamin B_{12}, antibiotics, and liver preparations have been suggested to counteract those toxic effects but have been generally ineffectual. Hemorrhagic diatheses from thrombocytopenia or ulcerations in the gastrointestinal tract present serious problems.

Another complication of therapy is resistance to certain preparations in human beings just as in the mouse experiments previously cited. Such resistance does not militate against use of other agents.

Perhaps the results with the use of folic acid antagonists can be summarized by reiterating that in some patients effects occur that have not been previously observed in acute leukemia. These favorable responses occur much more frequently in children than in adults, and their duration is variable but with no expectancy of cure. Other forms of leukemia are not favorably affected by these agents.

6-MP is an antimetabolite used in the treatment of leukemia. This substance acts as a purine antagonist against certain forms of bacteria, but its mode of action in leukemia is unknown, albeit apparently in a manner different from the folic acid antagonists. Burchenal et al.[822] have summarized their clinical evaluation of this agent in a very comprehensive review including the pharmacology, clinical results, and toxicology together with a series of representative case histories. The results appear to follow those obtained with folic acid antagonists with more strikingly beneficial results in children with acute leukemia, 15 out of 45 such patients showing good clinical and hematologic remissions and another 10 patients showing partial improvement. In adults remissions in acute leukemia have been only occasional, and temporary remissions have occurred in some cases of chronic myelocytic leukemia. The lymphomas, including lymphocytic leukemia and lymphosarcoma, were unaffected by 6-MP. In some instances of acute leukemia in children with resistance to folic acid antagonists or to ACTH or cortisone, 6-MP proved effective in producing some degree of remission. Resistance to 6-MP develops more rapidly than with the folic acid antagonists, but there is apparently no cross resistance between the two. Toxic effects were primarily hemopoietic, with leukopenia and bone marrow depression. However, there is cessation of this process on withdrawal of the drug. Gastrointestinal symptoms were generally mild and not of the order of severity of those produced by the folic acid antagonists. Tivey and Bross[823] summarized the results of a conference on therapy with 6-MP as follows.

Of 337 children with acute leukemia treated in 13 clinics, 36% were improved. The percentage varied from 13 in one clinic to almost 70 in another. Variables such as dosage schedules, terminology, and the use of other agents in conjunction with 6-MP made interpretation of the results difficult.

In this same report there is an illuminating block chart (Table 274) showing that as new compounds become available more children with acute leukemia survive 1 year or longer with treatment. Ordinarily 5% survive beyond 1 year; with Amethopterin and cortisone, approximately 30% carry on for 1 year or longer; with Amethopterin, cortisone, and 6-MP, 50% survive the year.

Urethane (ethyl carbamate) has been found an effective and relatively simple agent in the therapy of chronic myelocytic leukemia and in multiple myeloma. As with all the other chemotherapeutic agents, a host of papers on the subject may be found in both the domestic and foreign literature. It effects a lowering of the leukocyte count in chronic myelocytic leukemia and at times may cause some diminution in organ enlargements in this disease. Its greatest recommendation is the ease of administration (oral) and its relative lack of discomfiture. Toxic symptoms, other than those related to the hemopoietic system, are relatively mild and disappear upon withdrawal of the drug. Rare instances of severe liver damage may occur. Since leukopenia and thrombocytopenia of serious proportions may occur, treatment with urethane should be monitored with frequent observations of the blood picture. When the leukocyte count reaches normal levels, dosage should be diminished or lowered. Our impression is that urethane therapy holds a position in relation to the treatment of chronic myelocytic leukemia that arsenotherapy used to hold.

Nitrogen mustard (methyl-bis [β-chloroethyl] amine hydrochloride) is the mustard gas of World War I vintage and has had its rebirth as a chemotherapeutic agent in the treatment of the malignant lymphomas, being most successful in Hodgkin's disease. The nitrogen mustards are representative of a group of antileukemic agents categorized as radiomimetic. Although the mustards have been tried in many forms of leukemia, their effectiveness has been greatest in Hodgkin's disease, some cases of generalized lymphosarcoma, and perhaps have an occasional worthy application in other selected cases. The mustards are administered intravenously and may cause severe chemical phlebitis or severe reactions at the site of administration if accidentally infiltrated into the tissues. Nausea and vomiting of a disturbing degree are frequent toxic side reactions. There is considerable difference of opinion as to just where to place these agents in relation to roentgen radiation therapy. Generally speaking, there are few if any beneficial effects produced by the mustards that have not been produced by roentgen radiation. Relative costs do not appear a basis for choice. Although nitrogen mustard is less expensive, it is best handled under hospitalized conditions, adding to the cost of therapy. Toxic manifestations such as nausea and vomiting are much more frequent with mustards than with roentgen radiation. Toxic hematologic effects, particularly thrombocytopenia and leukopenia of severe degree, are more likely to occur after therapy with the mustards than with roentgen radiation. In general, when organ enlargements such as localized lymphadenopathy or splenomegaly of considerable proportions are present, direct radiation is much more likely to accomplish shrinkage of these organs than are the mustards. Pruritus, which may be very distressing in Hodgkin's disease, responds favorably more frequently to mustard therapy than to radiation therapy.

It is frequently claimed that when the malignant lymphomas become resistant to roentgen radiation the disease will still react favorably to the mustards and may become radiosensitive again. For this reason alternate courses of therapy with mustards and radiation have been recommended and in some investigations simultaneous therapy with both agents has been tried.

Triethylenemelamine (TEM) was the first of a group of ethylenimine derivatives having nitrogen mustardlike actions. Included in this group are triethylenephosphoramide (TEPA), triethylenethiophosphoramide (thio-TEPA), and diethylenephosphoramide (DEPA). The therapeutic effects with these substances are fairly similar to those seen with the nitrogen mustards, Hodgkin's disease being the most favorably affected, although some control of chronic lymphocytic and myelocytic leukemia has been effected. An advantage over the mustard therapy is that these agents may be given orally. Among the toxic effects, the most significant are related to suppression of hemopoiesis, with leukopenia and thrombocytopenia not uncommon. Cumulative toxic effects may reach serious proportions, and since there is a narrow margin of safety between desired clinical effects and toxic reactions, careful monitoring of the hematologic status of these patients is essential.

Myleran (GT 41) is one of a series of sulphonic acid and other esters which were synthesized,[824] particularly with the idea that they might exert nitrogen mustardlike biologic action. Galton[825] reported on the use of this agent in leukemia and found it effective in producing remissions in chronic myelocytic leukemia. Its major field of usefulness appears to be in this form of leukemia because of its depressive action on the myeloid series. Thrombocytopenia may be an important undesirable toxic effect.

Steroid therapy in the form of cortisone or corticotropin (ACTH) has been used in selected cases of leukemia and malignant lymphomas. One gathers the general impression that these agents are most helpful in those cases which have as an associated phenomenon some secondary immunohematologic features, such as hemolytic anemia, thrombocytopenia, or leukopenia. Consequently, these agents have not been used as primary weapons against such malignant disease but rather as adjunctive therapy along with other therapeutic approaches. Such situations arise frequently in the acute leukemias and in selected cases of chronic leukemias and malignant lymphomas in which splenic involvement is prominent. The incidence and character of toxic effects with ACTH and cortisone are similar to those accompanying their use in other disease processes. These include Cushing's syndrome (acne, hirsutism, edema, moon facies, hypertension, and glycosuria), mental depression, and psychoses.

Radiation therapy "is still the sheet anchor for treating chronic leukemias"[826] and, we might add, the treatment of malignant lymphomas. Radiation has been used in the form of external radiation or internal radiation (radioactive isotopes). Variations in dosage schedules and methods of application are numerous, with champions representing the various schools of thought. As with many other therapeutic procedures, the enthusiasm and persistence of the therapist color his views. The end results of radiation, regardless of method, appear to be about the same insofar as longevity and relief of symptoms are concerned. Toxic symptoms of external radiation include radiation sickness, which is seldom seen with isotope therapy. On the other hand annoying hematologic complications, such as severe leukopenia, anemia, and thrombocytopenia, are more frequent with isotope therapy than with external radiation. The shrinkage of organ enlargements, such as splenomegaly or lymphadenopathy, can be more effectively accomplished with radiation therapy than with isotopes.

The most frequently used isotope is radioactive phosphorus (P^{32}). This agent may be administered orally or intravenously. There is a period of approximately 3-4 wk. before therapeutic response is seen. Colloidal gold (Au^{198}) has been used in some cases of chronic myelocytic leukemia[827] and it has been tried in the treatment of effusions caused by malignant neoplasms.[828]

Radiation therapy is not used in the treatment of the acute leukemias. It has a very useful place in the malignant lymphomas, with external radiation generally favored over isotope therapy.

A host of miscellaneous forms of therapy has been reported with varying results. Myelokentric and lymphokentric acids[829] have been administered on the basis of the reciprocal actions of substances affecting the myelopoietic and lymphopoietic systems. Vitamin B_{12} and other hematinics have been generally found ineffective. In addition, a large number of chemicals known to produce leukopenia in animals and human beings have been given limited therapeutic trials.

Transfusions play a very important role in the management of the anemia associated with leukemia and malignant lymphomas. The ready availability of blood has been a major factor in the rehabilitation of many of these patients whose anemia generally does not respond to oral hematinics unless there is an associated blood loss. It is our opinion that many of the benefits of modern care of these patients can be attributed to the free use of whole blood.

Almost all of the antibiotics have been used as adjunctive therapy in the treatment of the leukemias. The display of these agents has embodied both prophylactic therapy and the treatment of actual infection. As one reads some of the literature, there is an overtone suggesting that the antibiotics might have some beneficial influence on the leukemic process other than those effects related to infection. Our experience is that in the absence of infection the antibiotics can play only a questionable role.

With the growing consciousness of immunohematologic mechanisms, more and more patients with leukemia and lymphomas are being considered for splenectomy. The patients with secondary hemolytic anemia are the ones in whom splenectomy has been frequently considered, especially in chronic lymphocytic leukemia. Poor results with splenectomy have been recently reported in 5 advanced cases of Hodgkin's disease.[830] It would appear that unless well-proved immunohematologic mechanisms can be demonstrated in an individual patient, splenectomy should not be considered. Splenectomy, when effective, affects only the abnormal immunologic process, and whatever benefits accrue to the patient are the result of such influences. The

Table 274. *Chemotherapeutic agents useful in treatment of neoplastic diseases**

Agent	*Average dose*	*Diseases benefited*	*Effect of overdosage: complications*
Urethane	0.5-1.0 gm.	Multiple myeloma Myeloid proliferative diseases Leukemia, chronic granulocytic Polycythemia vera?	Anorexia, nausea, vomiting, olfactory disturbance Leukopenia, pancytopenia (rare) Centrilobular hepatic degeneration and necrosis
Nitrogen mustard (HN_2)	0.1 mg./kg. I.V. 4-6 times	Lymphoid proliferative diseases Hodgkin's disease (generalized) Lymphomas, malignant Some anaplastic carcinomas	Acute nausea, vomiting Pancytopenia Bone marrow depression (temporary)
Triethylenemelamine (TEM)	2.5 mg., fasting with 2 gm. soda/day 2-3 times initially; 1-5 mg./5-10 day as maintenance	Chronic lymphocytic leukemia Lymphocytic lymphoma Hodgkin's disease (generalized) Chronic granulocytic leukemia Polycythemia vera Adenocarcinoma ovary	Anorexia, nausea, vomiting Leukopenia, severe Pancytopenia
ACTH	20 units I.V. for 15-18 hr./day, or 20-40 units gel I.M./day	Acute leukemia Chronic lymphocytic leukemia with marrow damage Hemopoietic malignancies with symptomatic hemolytic anemia	Edema Cushing's syndrome: moon facies, acne, hirsutism, edema, hypertension, hyperglycemia (glycosuria) Hypokalemic, hypochloremic alkalosis Mental depression, psychoses
Cortisone	25-50 mg. q 4-6 hr.	Same as ACTH	Same as ACTH
Folic acid antagonists	Aminopterin, 0.5-1 mg., orally, 1-3 times/week	Acute leukemia	Pancytopenia Mouth ulceration Diarrhea
6-Mercaptopurine (Purinethol)†	1-2.5 mg./kg., daily initially	Acute leukemia Chronic granulocytic leukemia	Leukopenia Pancytopenia
Myleran†	6 mg./day, orally initially; 2-4 mg./day maintenance	Chronic granulocytic leukemia	Leukopenia Pancytopenia

basic disease is usually unaffected, or the clinical course may be precipitated into a more rapid tempo.

In the choice of treatment of any patient a host of factors must be given consideration. Undoubtedly the philosophy of the therapist plays a leading role in such decisions. The utter pessimism of some physicians is understandable in the light of the death sentence imposed by a diagnosis such as leukemia or malignant lymphoma. The outlook has been brightened by the well-established effects of the antimetabolites in acute leukemia, in which events have taken place that were never seen before. These results have modified the views of many in the direction of achieving control of these diseases in somewhat the same manner as diabetes is controlled. The approach to such control in our present state of knowledge is limited to a great extent by the untoward reactions of the agents used in combating these diseases. There are many times when the natural course of the disease is better left undisturbed than overzealously treated to a point at which the discomfort from the therapy far outshadows that associated with the disease process. This implies a thorough knowledge of the natural history of the disease, which may be difficult to prophesy in individual cases but has been fairly well categorized in general.

Many studies on life expectancy have been published; there is no conclusive proof that life expectancy is prolonged by our present-day treatment, except perhaps in acute leukemia, especially in children. The pessimistic school has raised the question of whether such increases in prolongation of life as may occur are even worthwhile and point to the added mental anguish and economic strain imposed upon patients and family as sufficient reason to question the wisdom of this prolongation. Social conscience and philosophy become so inextricably enmeshed in these discussions that at times we lose sight of our position. The immature press releases of the optimistic school are as much to be abhorred as is the nihilistic approach of their opposites. There is undoubtedly a middle ground of approach in which the comfort and usefulness of the patient should be our present target of therapy. Judicious application of present technics can accomplish these aims in many cases. In the meantime the genius that will effect real cure has not been revealed to us. The furious attack on nucleic acid metabolism may or may not be the proper answer but indicates an attitude of refusal to be stifled by traditional concepts. Along with this attitude comes a ray of hopefulness that satisfactory answers may come in the not too distant future. Whence will come the prophets carrying the glad tidings remains to be seen.

Chapter 67

Bone marrow studies

JOHN D. BAUER

In all uncertain cases of blood diagnosis it is well to obtain some of the bone marrow for diagnostic examination.

In the adult human being the bone marrow of the long bones is yellow fat; the marrow is red (hematopoietic) **at birth.** In the early years, say about **7 yr.**, fat in small quantities appears; between **12** and **14 yr.**, a visible patch of yellow appears in the middle of the femur which increases until there is only a small patch of red marrow near the end of the diaphysis in the adult. The same phenomenon takes place in the tibia, ulna, radius, humerus, and fibula. The only red marrow which persists in the adult is to be found in the bones of the skull, ribs, vertebrae, sternum, and the innominate bones. Bone marrow studies, therefore, are most conveniently made from the adult sternum.

The bone marrow in infants shows many immature cells. In the **6 mo. fetus** the red cells make up three-quarters of the total; **at 8 mo.**, nine-tenths; and **at term**, the red and white cells are equal. Latimer and Mayerhoff found fetal marrow containing 2-22% granulocytes. Doan and Zerfas state that during the first year of life the marrow contains 4-20% lymphocytes. In embryonic life the ratio of erythroid to myeloid elements is 100:1. In adults, it is 1:3. Since the red bone marrow of newborn children contains many more immature cells than adult bone marrow, it is easy to understand the ready appearance of immature cells in the circulating blood of an infant following slight stimuli. In children, the number of cells in the bone marrow varies from 270,000-1,568,000/ml. In adults we find that in the total bone marrow volume of 1500 ml. in the human body the myeloid elements outnumber the erythroid elements 3:1; most of the myeloid cells, 85%, are the myelocytic cells with their full quota of granules.

There is a diurnal variation in leukocytes with an afternoon and a midnight rise. The bone marrow delivers granulocytes, myelocytes, juvenile cells, and stab cells hourly, but especially at the interval at which the leukocytes in the blood stream are increased. The maturation time from myelocytes to more mature forms is probably from 45 min. to 2½ hr.

One per cent of the bone marrow elements are megakaryocytes. According to Wright these constitute the origin of blood platelets. In bone marrow, 70% of the total erythroid cells are normoblasts; erythroblasts, 26-30%; proerythroblasts, 1-4; and megaloblasts, 0.01-0.04%. According to Schilling the megaloblasts represent a stage in the development of the red cells, but according to Ferrata and Michaelson, the megaloblast is present in the bone marrow only in pernicious anemia. They do state, however, that the cell which is sometimes mistaken for the megaloblast is in reality the proerythroblast. Sabin and Doan corroborate Schilling's claim that the megaloblast is present in normal bone marrow but only in very small numbers.

Reticulated red cells and normoblasts are released into the blood stream at regular intervals; the red cell count varies about 1,000,000/c.mm./day. The high point of bone marrow delivery is in the morning and afternoon, not afternoon and midnight, as is the case with the white blood cells.

SUMMARY OF NORMAL BONE MARROW FINDINGS

What is the normal cellular content of the bone marrow? We must assume, first, that under normal conditions myelopoiesis and erythropoiesis are confined to the bone marrow. Lymphocytopoiesis normally does not seem to be confined to the bone marrow. The investigations of Askanazy, Oehme, von Fischer, and others showed that there are fully developed lymph follicles in the bone marrow in a large number of cases. Under normal conditions, however, lymphocytopoiesis seems to have no connection with either erythropoiesis or myelopoiesis although there is no objective hematologic proof of this. The Schilling followers do not believe that monocytopoiesis is connected with bone marrow function. Monocytes are seen in very few numbers in bone marrow according to Schilling, Sabin, and others. Yamamoto and Schilling[831] have shown in man and in animals that the composition of different parts of the marrow is practically the same on the same occasion in the same individual. In a few cases peripheral eosinophilia occurred which was accompanied by an increase in the proeosinophils in the bone marrow. On the other hand abnormally low numbers of peripheral eosinophils were not represented by low values in the marrow. According to these authors parallelism does not exist between peripheral and bone marrow eosinophilia. Homma[832] found constant bone marrow eosinophilia with an elevation in the number of peripheral eosinophils. But conversely there may be normal or somewhat increased numbers of eosinophils in the bone marrow in spite of decreased number of peripheral eosinophils. Magne is substantially in accord with Homma. Barta found that the effect of toxin on eosinophils is exerted on the fully developed cells which have wandered out and not on the young forms in the marrow which explains the decreased number of peripheral eosinophils without a corresponding decrease in the eosinophils of the bone marrow. Table 275 gives the composition of bone marrow according to a number of authorities.

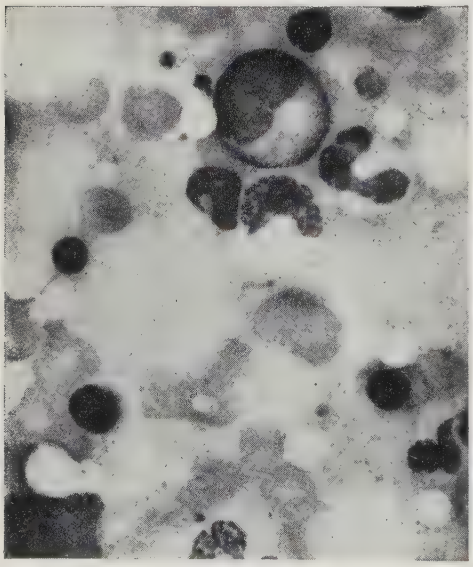

Fig. 455. Normal bone marrow. Note lack of crowding of cells and presence of fat. (×950.)

Holmes and Broun[833] call attention to the mitotic divisions of cells in the bone marrow spreads made by them as being limited to an intensely basophilic cell which varies in morphology from both the typical myeloblast and the typical megaloblast. They have called this cell the primitive cell in their differential counts. They occasionally noted mitotic division in hemoglobin-containing erythroblasts. **Differential counts** by these writers **of bone marrow elements** in 7 cases with normal peripheral blood pictures were as follows: myeloblasts, 2.4%; myelocytes, 7%; juvenile cells, 6.7%; stab cells, 14%; II segmented neutrophils, 10%; III segmented neutrophils, 6.3%; IV, V, etc., segmented neutrophils, 1.1%; eosinophils, 1%; basophils, 0.3%; monocytes and reticuloendothelial elements, 9%; lymphoid cells, 24.9%; megaloblasts, 5.2%; normoblasts, 6.9%; primitive cells, 2.6%. These findings agree rather closely with those of Arinkin[834] on similar types of cases.

It is interesting to note that the high percentage of immature granulocytes in their counts confirms the concept of Arneth and Schilling that the neutrophilic nucleus changes progressively with age from the round to the segmented form. The high percentage of juvenile and stab cells confirms the idea that these are young granulocytes.

An examination of Table 274 and similar tables in other publications reveals wide variations in opinions on the relative percentages of various cells, and raises some question as to the value of doing differential counts routinely on bone marrows. We are inclined to agree with Israels[835]: "The variability of the normal bone marrow means, in effect, that only gross differences can be taken to indicate pathological change, and this in turn raises a question of whether it is worthwhile

Table 276. *General comparison of spreads and sections of bone marrow*

	Spreads	*Sections*
Cellularity	Varies with technic	Consistent with true state of marrow
Relative distribution of cell species	Irregularities dependent on technic	Accurate reflection
Identification of individual cells	Better than in sections	More difficult than in spreads
Mitotic activity	Morphology of individual mitotic figures better than in sections	Quantitative aspect more readily apparent than in spreads
Histologic structure	Only implied	Readily discerned
Cytochemical studies	Material unsatisfactory	Material satisfactory
Lymphomas	Easily missed or not apparent	Readily identified
Granuloma lesions	Not seen	Readily identified
Malignancy	Individual cells or groups of cells irregularly distributed	Syncytial masses readily found; histologic arrangement may indicate source

to undertake, in every case, the time-consuming differential count . . . this practice has now been given up for a 'qualitative assessment' in all except the most difficult cases, or in research studies. Such a qualitative assessment is adequate for diagnosis in most instances, and gives a far clearer idea of the over-all marrow picture than does a row of figures, especially since few physicians or pathologists carry the normal figures around with them."* We have used an assessment type of reporting clinical marrow aspirations and include the following data in such reports:

Cellularity: Normal, increased, or decreased.

Predominant cell type: Normally this should be members of the myelocytic series.

Myelocytic series: Normally shows predominance of older forms, e.g., stab and segmented cells, with a gradual diminution to myeloblasts. If a left shift is present, comment is made on the degree. Qualitative changes in the cells of this series are described if present. Such changes include toxic granules and abnormal forms. The myeloid-erythroid ratio is estimated.

Erythrocytic series: Normally shows predominance of older forms, e.g., orthochromic normoblasts with a scattering of younger forms. If a shift has occurred to younger members of this series, its degree is appraised and reported. The type of erythropoiesis is described, e.g., definitive (as in normal red blood cell development) or primitive (as in pernicious anemia and some other markedly pathologic states). Qualitative changes indicating pathologic erythropoiesis are noted. These include marked poikilocytosis (poikilocytes, spherocytes, target cells), anisocytosis, basophilic stippling, abnormalities of nuclear morphology (karyorrhexis, karyolysis), and abnormal relationships of nucleus to cell size.

Lymphocytic series: Normally less than 10%. Quantitative or qualitative changes in these cells are noted.

Megakaryocytic series: Normally mature megakaryocytes are readily found, especially in the thin and thick ends of spreads. They tend to be fewer in the middle of spreads. Qualitative changes such as cytolysis with loss of platelet formation are described.

Other cells, such as fat cells, reticuloendothelial cells, and "cells foreign to normal bone marrow (tumor cells)" are noted.

Mitoses are noted as to frequency, and comment is made as to whether mitotic figures are normal or abnormal in appearance.

Such appraisals are not based on spreads alone. Agress[836] has shown the value of studying sections and spreads simultaneously in order to obtain a true quantitative evaluation of bone marrow. A general comparison of the two methods is shown in Table 276 by Agress, which is based on his study of 1187 cases in which bone marrow aspirations were performed.

As can be readily noted from Table 276, many differences are apparent between spreads and sections. Perhaps the outstanding difference relates to quantitative appraisal.

It is not unusual to find spreads which appear extremely hypocellular, whereas the sections may appear quite normally cellular. On the other hand, individual cell morphology is more clearly studied in well-prepared spreads.

In this study a correlation between spreads and sections of bone marrow was set up by Agress in relation to their being diagnostic. Table 277 represents this correlation.

There is close correlation between spreads and sections insofar as the over-all percentage in satisfactory preparations is concerned. However, in individual cases the spread may be unsatisfactory and the section satisfactory. In other instances, the reverse may be true. This correlation is particularly important in the hypoplastic or aplastic states. Note that no cases of aplastic anemia were diagnosed on spreads alone and only 20% were diagnosed on sections of the clot obtained by routine

*Diagnostic.

marrow aspirations. The reason for this should be obvious. In those cases of aplastic anemia in which the bone marrow is almost completely replaced by fibrous tissue, routine marrow aspirations are generally doomed to failure. This diagnosis should not be made on the **absence** of cells from the spread **alone.** If sections of clot show no marrow units, the diagnosis still should not be made since the result may be purely technical in origin. In such an event, the marrow aspiration must be repeated or surgical trephine should be performed to obtain a truly representative specimen of bone marrow. This figure also gives some suggestion of what the physician might expect diagnostically from bone marrow aspiration.

Like all other laboratory examinations, bone marrow studies have their limitations and serve their most useful purpose only when correlated with the clinical aspects of the patient. Bone marrow aspiration should not be performed prior to a thorough history, physical examination, and at least routine laboratory studies. This is particularly true in the vast majority of anemias, except pernicious anemia and a few others. In relation to pernicious anemia and related macrocytic anemias, it is important to remember that erythrocyte maturation factor in even modest dosages will convert the bone marrow picture considerably. For this reason, folic acid, liver, and vitamin B_{12} should not be administered prior to marrow aspiration. In Table 278 by Agress is given an outline of the indications for marrow aspirations. The cases listed under hypersplenism[837] are particularly to be stressed since these are conditions in which splenectomy may exert a very favorable influence.[837] It is well to remember that selected cases displaying the features of hypersplenism may be primarily due to metastatic carcinoma of the bone marrow. Splenectomy could serve no useful purpose in such cases. For this reason, bone marrow aspiration should be performed in all cases in which splenectomy is contemplated as a form of treatment for a blood dyscrasia. It has been our experience generally that the best results in these conditions come in those patients whose bone marrow contains a normally active or hyperactive picture of the blood element or elements affected. For example, we do not recommend splenectomy in idiopathic thrombocytopenic purpura unless the bone marrow shows a fairly good representation of megakaryocytes. Using this criterion alone our results with splenectomy have been exceedingly favorable. Much has been written about the bone marrow picture in idiopathic thrombocytopenic purpura as related to splenectomy, and there is no evidence other than the presence of adequate numbers of megakaryocytes (mature or immature) upon which the many observers will agree.

The second group of conditions with a bizarre blood picture forms a rare heterogeneous group that covers the horizon of medicine. It includes individual cases of drug intoxication, familial cell defects, or the unusual reflection of some well-known disease. It may include leukopenias or hyperleukocytosis as well as unusual cells in the peripheral blood. Abnormal forms of erythrocytes as well

Table 278. *Indications for bone marrow aspiration*

I. Every case of hypersplenism
    A. Thrombopenia
    B. Hemolytic anemia
    C. Leukopenia
    D. Emphatically when A, B, and C are combined (Splenectomy should not be performed in these cases without examination of bone marrow)
II. All cases with a persistent bizarre blood picture
III. Cases in which there is a high index of suspicion of marrow invasive disease, e.g., carcinoma, myeloma, Gaucher's disease, etc.
IV. Corroboration of a limited number of cases of leukemia in which peripheral blood studies are inconclusive
V. Macrocytic anemias of all types prior to therapy with erythrocyte maturation factor
VI. Malignant lymphomas in which lymph nodes are either unavailable or inconclusive
VII. A limited number of infections, e.g., brucellosis, histoplasmosis, tuberculosis, malaria (very rarely), leishmaniasis
VIII. All primary refractory anemias (repeated dry taps may require trephine)

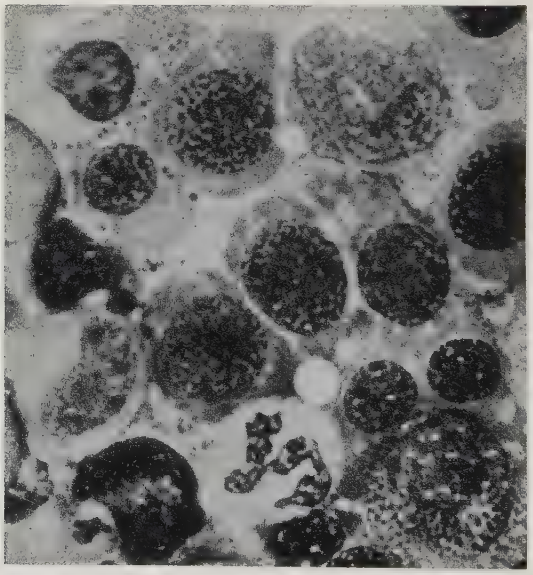

Fig. 460. Pernicious anemia, bone marrow, showing abnormal number of megaloblasts. (×950.)

as unexplained anemias should be included here. Thrombocytopenias or morphologically abnormal platelets (giant platelets) are included. Many of these cases are associated with organ enlargements such as the spleen and liver, suggesting some blood dyscrasias. Some of these cases are examples of hypersplenism, and as our knowledge of immunohematology broadens, they are being more accurately categorized. Some of these cases are in reality malignancies, with or without demonstrable bone marrow metastases.

The diagnosis of bone marrow invasion by metastatic carcinoma is dependent upon a number of factors, most important of which is a high index of suspicion. In our experience, the finding of **one or more normoblasts in the peripheral blood of an adult not having an obvious disease explaining the presence of normoblasts** is one of the most important **indicators of possible malignant invasion** of the bone marrow. Not all cases of bone marrow malignancy show normoblasts in the peripheral blood, but when normoblasts are present, we pursue the possibility of malignancy vigorously. Agress uncovered 2 cases of unexpected malignancy with normal blood values in which normoblasts were found on routine blood spreads. The success with which marrow aspiration will reveal metastases is dependent upon the vigor with which such searches are made. If multiple sites are aspirated and numerous slides are examined, the positive results may be very high. Sections of bone marrow clot often will show tumor cells otherwise difficult to find in spreads alone. The section technic outlined by Agress may also give some information as to the original site of the malignancy by the histologic structure assumed by the tumor cells.

MULTIPLE MYELOMA

Multiple myeloma is a form of malignant tumor occurring in the skeletal trunk of adults and infiltrating the marrow cavity of numerous bones. It has been found in people within the age group of 30 to 75 yr., the greatest incidence being at the age of 35 yr. It affects the ribs and spine and the upper ends of the long bones, but the flat bones of the skull and pelvis may also be implicated. There are 4 types of myeloma: the plasma cell type, the myelocytoma, the lymphocytoma and the erythrocytoma. At the present time we accept these morphologic variations as evidence of varying degrees of maturation of plasmablasts and consider them to be devoid of any clinical importance. Geschickter and Copeland[838] gave 6 cardinal signs, 2 or more of which they thought were constantly present. These were as follows: "(1) multiple involvement of the skeletal trunk in an adult, (2) pathologic fracture of rib, (3) excretion of Bence Jones bodies, (4) characteristic backache with signs of early paraplegia, (5) an otherwise inexplicable anemia, and (6) lower nephron nephrosis with high nitrogen retention, low blood pressure, and high serum proteins."* Cases have been reported with none of these signs present. Beizer et al.[839] point to other characteristic signs of this disease, as follows: (1) hyperproteinemia, with reversal of the albumin-globulin ratio, (2) hypercalcemia with normal or high serum phosphorus, (3) evidence of autohemagglutination in the counting chamber, on blood films, or detected by the cayenne pepper appearance of blood in the small vessels of the fundus when viewed through the ophthalmoscope while pressure is being placed on the eyeball, and (4) the appearance of an anticomplementary reaction when a complement-fixation test is being carried out. That none of these signs is pathognomonic is obvious.

Mistakes are easy when dealing with a supposed case of multiple myeloma. These cases may be mistaken for metastatic skeletal lesions, hyperparathyroidism, spondylitis, nephritis, and leukopenic leukemia, or vice versa. Quite frequently the suggestion of the existence of this disease comes from a suspicious x-ray picture.

Bone marrow findings

Confirmation may be made by sternal puncture. Rosenthal and Vogel[840] state: "A definite diagnosis of multiple myeloma is possible during life only when made by means of sternal biopsy or the more simple aspiration method of Arinkin."† Beizer et al.[839] studied 10 cases. In 4 cases backache was the principal symptom. In one case, cervical pain was present and in another case arthralgia. Three cases sought relief of an existing anemia. In 7 of the 10 cases, x-ray photographs suggested the diagnosis.

A modified Arinkin method was used by these workers. From 1-1½ ml. were aspirated from the sternal marrow into a paraffin-lined

Plasma cell myeloma

test tube containing a small amount of heparin. Spreads were stained by Wright followed by Giemsa stain. Diagnosis is confirmed by finding typical myeloma cells. An increase in the typical and atypical plasma cells is also suggestive of multiple myeloma. However, these investigators very properly caution that an absence of these findings in sternal marrow does not rule out the diagnosis.

Myeloma cells show an abundant definitely outlined and deeply basophilic cytoplasm a moderately sized round eccentrically placed nucleus having a fairly coarse chromatin sharply demarcated from the parachromatin, and a very large nucleolus.

Beizer calls attention to the fact that minor variations from this description may exist. The amount of cytoplasm varies from a narrow rim about the nucleus to a large quantity. Multiple small vacuoles may occur. A perinuclear zone may be seen. In one case they found 27.5% plasma cells. These plasma cells had an eccentrically placed nucleus containing coarse clumps of chromatin, and a few cells with somewhat larger nuclei but no nucleoli were seen. They emphasized the fact that the myeloma cell shows a large nucleolus and that in examinations of over 160 bone marrows no such cell was ever found in connection with any other pathologic process. Our own experiences convince us of the accuracy of Beizer's observations as to the specificity of the myeloma cells and also as to the occurrence of many plasma cells in this condition (Fig. 462).

Bayrd and Heck[841] mentioned that a negative diagnosis resulting from sternal aspiration is not always adequate evidence for excluding the possibility of multiple myeloma. Changes in the bone marrow may be irregularly distributed rather than diffuse, and the results on repeated aspirations are not uniform. In one instance in their experience a third aspiration of marrow was necessary to secure a diagnostic specimen.

So far as myeloma cells or atypical plasma cells are concerned, Osgood and Hunter[842] found 45-54% of plasma cells in one case in a 49 yr. old man. Osgood and Hunter considered this to be a true instance of plasma cell leukemia and not multiple myeloma with myeloma cells in the peripheral blood. They held splenomegaly, epistaxis, bleeding from the gums, and the clinical course which this patient pursued to be of the type characteristic of leukemia. As further evidence they cited the lack of Bence Jones proteinuria and of typical defects of the bone in the roentgenograms, bone pain, and bone fragility. Others have felt that this is a distinction of degree only, not of kind. With this opinion Bayrd and Heck concur.

Meyer et al[843] reviewed all the known cases of multiple myeloma in which there were plasma cells in the peripheral blood and all the purported cases of plasma cell leukemia, of which they listed 4. In a careful consideration of these cases they expressed doubt that any were actually cases of true plasma cell leukemia. They rejected these cases largely on the ground that the absence of osseous lesions had not been adequately established. They did report one case which they considered to be a true case of acute plasma cell leukemia although they considered it to "complete the chain in the analogy to lymphoid tumors" such as lymphoma and lymphocytic leukemia.

Diagnosis

The various clinical and laboratory features of multiple myeloma disease are striking, and the occurrence of multiple osteolytic lesions of the bone, Bence Jones proteinuria, and hyperproteinemia is strongly suggestive evidence for the presence of multiple myeloma. However, as pointed out by Bayrd and Heck, every effort should be made to confirm this with pathologic material for the sake of accuracy of prognosis and suggestions as to an outline of treatment. To this end, because of its simplicity and broad diagnostic range, the method of sternal aspiration readily lends itself.

Diagnosis of multiple myeloma can often be made by bone marrow aspiration. In this disease, the normal bone marrow elements are replaced by large numbers of plasma cells. When the percentage of plasma cells is quite high (40-90%), the diagnosis is relatively simple. However, there are many instances in which lower incidences of bone marrow plasmacytosis (up to 20%) may leave some doubt as to the diagnosis. We have had an experience corroborating that of others[844] that an increase in plasma cells may occur in a large heterogeneous group of chronic diseases, such as pulmonary tuberculosis, malignancy (with or without marrow invasion), rheumatoid arthritis, syphilis, sarcoidosis, cirrhosis of the liver, gold intoxication, Banti's syndrome, bacterial endocarditis, periarteritis nodosum, myelofibrosis, chronic leukemias (especially when irradiated), and diseases either members of or simulating collagen disease. A rather interesting feature of many of these cases is that they display disturbances of blood protein relationships, often showing elevations of the globulin fraction. In none of these secondary plasmacytoses have we seen the very abnormal plasma cells found in most cases of multiple myeloma. These myeloma cells, as they are referred to by some observers, are larger than normal plasma cells, ranging from 15-18μ in diameter, and have a slightly pinkish cast to the cytoplasm. However, other cases of myeloma have plasma cells indistinguishable from normal plasma cells. In general, abnormal forms with 2- to 6-lobed nuclei are much more common in myeloma than in the reactive plasmacytoses although we have occasionally found trilobed plasma cells in the latter. Mitoses may be quite common in myeloma and are often abnormal in configuration, as is frequently true in many malignant diseases.

Sections of the bone marrow are helpful in isolated cases of multiple myeloma of the nodular type. In such instances spreads might not show an increase in plasma cells, but the sections may show solid nodules of myeloma cells. In other instances the marrow may be exceedingly fatty, and the spreads give an impression of extreme hypoplasia with very few cells seen. The sections in such cases show the true character of the disease.

The myeloma cells frequently contain various inclusions such as amyloid or paraamyloid, crystalline substances, and ribonucleotides called **Russell bodies.**

Of clinical importance is the so-called single plasmacytoma and the extramedullary plasmacytoma; both lesions, which by varying periods of months to years, precede the development of generalized multiple myeloma.

The serologic and clinicopathologic findings of multiple myeloma are described in the appropriate section.

MACROGLOBULINEMIA OF WALDENSTRÖM

This disease presents a unique mixture of plasmacytic and lymphocytic neoplastic proliferation.[846]

Clinically these patients show hemorrhagic diathesis and enlargement of the liver and spleen and at times of lymph nodes.

Laboratory findings

Hematologic findings: The disease is characterized by an anemia which may vary from moderate to severe. The dysproteinemia is responsible for the hemolytic component, which leads to the appearance of immature red cells in the peripheral blood, and for hemorrhagic manifestations of the disease.

White blood cells: The total white cell count as well as the differential count are usually within normal limits. This point is all the more interesting since the clinical appearance of the patient with enlargement of the liver, spleen, and lymph nodes and with hemorrhagic diathesis readily suggests the diagnosis of leukemia.

Bone marrow: The entire bone marrow is infiltrated by lymphocytes which either are mature or show various transition forms from reticulum cells to plasma cells. The plasma cells are collected in small foci or are distributed diffusely throughout the bone marrow. Frequently there is also an increase in tissue mast cells.

Coagulation work-up: There are a few reports which tend to show defects in various coagulation factors, but it is generally accepted that the bleeding tendency is related to the macroglobulinemia.

Sedimentation rate: The sedimentation rate is markedly increased.

Nonhematologic findings: In addition to the bone marrow findings, the protein changes within the serum[847, 848] are the most diagnostic criteria of macroglobulinemia. The serum contains an increase in total protein which is mainly due to an increase in globulins. Paper electrophoresis frequently shows the appearance of an abnormal globulin which may be found in the alpha, beta, or gamma position or between the beta and gamma bands. It is similar to the peak found in the electrophoretic pattern of multiple myeloma and is therefore labeled M globulin. By methods other than paper electrophoresis, this M glob-

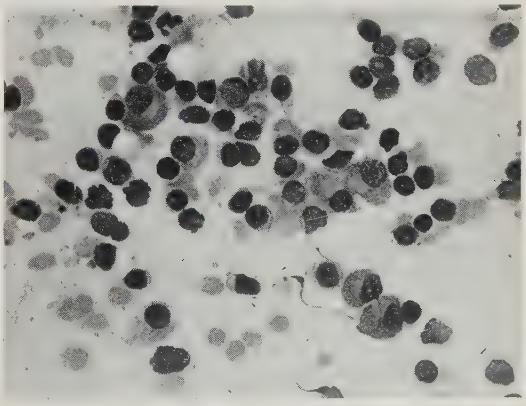

Fig. 463. Bone marrow in macroglobulinemia.

ulin of macroglobulinemia can be separated from the M globulin of multiple myeloma.[849, 850, 850a] Ultracentrifugation characteristically shows an increase in macroglobulins over 5% (normal values, 2-3%). The presence of macroglobulins can also be demonstrated by immune electrophoretic methods. Apart from macroglobulins, the serum may also contain paraproteins and cryoglobulins. The presence of these abnormal proteins leads to a marked increase in the viscosity of the serum which at times is more marked at lower temperatures than at room or body temperature.

The abnormal proteins may lead to false positive serologic tests for syphilis.

Urine: Proteinuria is found.

Laboratory tests for evaluation of serum proteins in macroglobulinemia

Sia test (euglobulin): If 1 drop of serum is added to distilled water, it is precipitated as white, cloudy material, whereas normal serum may produce slight clouding in the distilled water but no precipitate. This test is easy to perform but is not diagnostic of macroglobulinemia since it may be positive in multiple myeloma and other cases of dysproteinemia.

Formol-gel test: Add 1 drop 40% formalin to 0.5 ml. serum. If the test is positive, the serum will gel within a few minutes.

Weltmann band: According to Kappeler et al.[845] the band in macroglobulinemia is shortened, whereas in multiple myeloma it is lengthened.

Pathophysiology

Our present concept is that macroglobulinemia represents a malignant form of lymphoid, plasmacytic, and reticulocytic proliferation. It may occur as a primary malignant form in an acute or more chronic phase. It may also occur secondarily (symptomatically), accompanying such diseases as lymphatic and myelogenous leukemia, lymphomas, various malignant tumors such as carcinomas and sarcomas, and liver diseases.

HODGKIN'S DISEASE

Hodgkin's disease has a fairly high incidence of marrow involvement in studies in which extensive autopsy search has been performed. However in routine bone marrow aspirations, the yield is disappointing. An increase of reticuloendothelial cells with an eosinophilia is suggestive. Rarely, sections of the marrow will reveal the typical Hodgkin's nodule. Out of 46 proved cases of Hodgkin's disease, in only 4 cases were Hodgkin's nodules found, and in all these instances serial sections of the marrow clot were searched vigorously. As with other marrow lesions with a spotty distribution, the success in finding such lesions is dependent in great part on the multiple sites and the search of many sections.

There are scattered reports of Reed-Sternberg cells being found in the bone marrow and peripheral blood. The morphologic identification of these cells is made more difficult by the fact that they resemble young megakaryocytes and that megakaryocytes are frequently increased in Hodgkin's disease. A differentiating feature is that Reed-Sternberg cells are PAS-negative, whereas megakaryocytes readily stain with PAS stain.

LEUKEMIA

Leukemia in almost all forms can be readily diagnosed by study of the peripheral blood. The most common exception to this is the acute stem cell leukemia with a low white blood count. We have found such cases in all age groups from 2 to 84 yr. but have seen it most frequently in the third and fourth decades of life. Organ enlargements, such as splenomegaly, hepatomegaly, and lymphadenopathy, are frequently absent or tend to be minimal. Anemia is usually quite obvious clinically, and the erythrocyte counts are down to 1,500,000 or 2,000,000 red cells/c.mm., with correspondingly low hemoglobin values. Hemorrhagic manifestations are a frequent accompaniment of the disease and reflect striking thrombopenia. Leukocyte values have ranged from 400-2000/c.mm. In all these cases we have been able to find leukemic cells in the peripheral blood, with varying effort required in individual instances. In some of these the leukemic cells have been only a small percentage of the cells in the peripheral blood. The diagnosis of leukemia could be made on peripheral blood studies alone. However, bone marrow aspiration readily corroborated our impression. In all these cases the marrow was exceedingly hypercellular, with an almost complete replacement of normal marrow elements by the leukemic cells. The striking difference between the cellularity of the bone marrow and the peripheral leukopenia in this condition raises a basic question as to what factors determine the delivery of cells from the bone marrow to the circulation. One would certainly expect tremendous leukocytosis in this condition. Perhaps peripheral destruction due to unknown immunohematologic factors plays a role in the leukopenia, anemia, and thrombopenia.

In the **chronic leukemias** there is fairly good correspondence between the peripheral blood changes and the bone marrow picture.

The marrow tends to be hyperplastic, with the increase in cells corresponding with the cell type in the peripheral blood. The degree of shift to younger forms is inclined to be more pronounced in the bone marrow than in the peripheral blood. It is not too unusual to see this disparity in chronic myelocytic leukemia, in which only a few myeloblasts are present in the peripheral blood but the bone marrow may show many such cells. In chronic lymphocytic leukemia approximately 85% of our cases showed typical leukemic hyperplasia. In the other 15%, lymphocytic increases were noted but the marrow was not completely replaced by abnormal lymphocytes. Cases of chronic lymphocytic leukemia, which were effectively treated with x-ray therapy, often showed so few lymphocytes in the bone marrow as to make the diagnosis of leukemia impossible. This was only rarely true in chronic myelocytic leukemia in which even though the marrow became less hyperplastic the monstrosity forms of leukemic development were qualitatively readily identifiable.

Monocytic leukemia, especially in the subleukemic and chronic forms, could usually be diagnosed by the presence of an increase in abnormal monocytes in the peripheral blood. However, our experience with such cases has been that it is not unusual to find only 12-25% of such cells in the peripheral blood. When the increment of increase was in the lower ranges, there were occasions when some doubt was cast on the validity of the diagnosis of monocytic leukemia. In all these cases the bone marrow showed a hyperplastic state due to an overabundance of abnormal monocytes.

The diagnosis of such rare entities as **erythroleukemia (Di Guglielmo's disease)** cannot be made except with the aid of bone marrow aspiration. In addition to hyperplasia of the bone marrow due to an increase in cells of this series, there are qualitative changes in the red cell development of extreme pathologic character. Monstrosities are numerous and consist of abnormal sizes, shapes, and nuclear structures of the red cells. Some cells reach the giant proportions of 35-40μ and have as many as 5-8 nuclei. There is marked asynchronism between cytoplasmic and nuclear development and mitotic figures are often abnormal.

PERNICIOUS ANEMIA

Bone marrow aspiration studies in the anemias are generally not very fruitful from a diagnostic standpoint. Perhaps they are of greatest assistance in the macrocytic anemias, with pernicious anemia the most outstanding example. In this condition the classical bone marrow picture can be seen under the following conditions: (1) a red blood cell count of 3,000,000/c.mm. or less and (2) no administration of erythrocyte maturation factor (liver, folic acid, or vitamin B_{12}). When the red cell count is above 3,000,000/c.mm., the typical bone marrow picture is rarely present, and as the red cell count increases, there is less and less likelihood of finding a typical picture. We have encountered cases displaying the typical neurologic syndrome of pernicious anemia with little or no anemia. Bone marrow aspirations in these cases have been of no help in diagnosis. Insofar as the effect of therapy is concerned, it is well to remember that even modest dosages of erythrocyte maturation factor will quickly alter the bone marrow picture so that within 24-48 hr. after such therapy it may be difficult to make a diagnosis of pernicious anemia. Whenever the diagnosis of pernicious anemia is even suspect, no liver or similar therapy should be administered before the marrow aspiration has been performed. Since such a diagnosis is so important in committing a patient to lifelong therapy, anything that interferes with an accurate diagnosis is to be avoided. Early diagnosis and adequate therapy are the only certain means of avoiding serious neurologic complications. Suboptimal therapy may mask the hematologic picture, whereas these neurologic features stealthily impose themselves on the patient. Once they are firmly established, even the most vigorous treatment may fail. These are but a few of the reasons for accurate diagnosis of pernicious anemia.

The bone marrow in **pernicious anemia in relapse** is markedly hyperplastic. When the marrow puncture is being performed, many cases display tenderness of the sternum. As the marrow material is removed, its hyperplastic character can be seen grossly. Spreads of the bone marrow readily reveal this hyperplasia, which is primarily erythrocytic. The myeloid-erythroid ratio is obviously altered, approaching a 1:1 ratio in most cases and even showing a 1:2 or 1:3 ratio in other instances. Erythropoiesis is of the primitive type, simulating that of the embryo in the prehepatic stage. There is a marked shift to younger forms as evidenced by the appearance of megaloblasts. Not only is there seen a profusion of megaloblasts, but there is also noted a marked increase in other young forms, such as basophilic normoblasts and polychromatophilic normoblasts. Pathologic erythropoiesis reaches its greatest proportions in the bone marrow in pernicious anemia, being approached only in the rare cases of Di Guglielmo's disease or other leukemic disease. These pathologic changes affect the cytoplasm as well as the nuclei of the red cells and consist of the following changes.

Abnormal cell size: The megaloblast itself begins as a giant form, usually measuring 20-24μ in diameter. There is little wonder, then, that the offspring of this cell are large. This developmental defect accounts for the macrocytosis.

Asynchronism of development: In normal cell development, cell size, cytoplasmic staining, and nuclear size keep pace in an orderly manner. In pernicious anemia, this synchronism disappears. Large cells with small nuclei are common. Many cells may display an extremely basophilic cytoplasm and have the nuclei of fully developed normoblasts.

Karyorrhexis of nuclei: Fragmentation of nuclei at all stages of development is readily apparent. This may vary from simple binucleated cells to erythrocytes containing one large nucleus surrounded by single or multiple Howell-Jolly bodies. Other red cells may display Howell-Jolly bodies only.

Karyolysis of nuclei: Whereas normal nucleated red cells show karyolysis of the nuclei by a diminution in size, the erythrocytes of pernicious anemia frequently display this phenomenon within the nucleus. As a result, the stained nucleus takes on a soil erosion appearance, showing alternating areas of well-stained chromatin alongside areas which do not stain at all or stain a reddish hue. Not only can this phenomenon be seen in sizeable nuclei, but it is also often visible in Howell-Jolly bodies.

Mitotic activity: This is exceedingly great and is abnormal. The abnormalities take on many bizarre features. It is not unusual to see 1 or 2 chromosomes off by themselves in one part of a cell away from the the major mitotic figure. When the mitotic figure shows separation of the chromatin, 1 pole may show considerably more material than the other. Abnormal condensations of chromatin are often noted, and lysis of the chromatin in mitotic figures (just as in the intact nuclei) is observable.

There is a feature of pernicious anemia bone marrow that is mentioned fairly frequently but is rarely stressed, even in hematology texts, and this relates to the **abnormal leukocyte development** in this disease. This pathologic myelopoiesis is as regularly occurring in pernicious anemia as are the red cell changes, and it disappears with specific therapy just as promptly as the abnormal erythropoiesis. The most striking abnormality is the finding of giant white cells, particularly notable at the promyelocyte, myelocyte, and juvenile stages, reaching a size of 20-22μ in diameter. In many of these cells there is often an inordinately great amount of nuclear material, giving the impression that the cell has all that it can do to contain the nucleus. When such cells go on to full maturity, they typify the pernicious anemia neutrophil with its increased size and multilobulated nucleus. Mitoses in the myelocytic series are increased and occasionally are abnormal.

The only other macrocytic anemias that we have encountered which are indistinguishable from pernicious anemia have been observed in tropical and nontropical sprue and in a rare case of *Diphyllobothrium latum* infestation. In all other instances, the differential diagnosis has been relatively simple. Advanced liver disease, such as cirrhosis, is occasionally associated with a macrocytic anemia. In none of the cases we have studied have we seen the degree of pathologic erythropoiesis and myelopoiesis observed in pernicious anemia in relapse. Macrocytosis may be striking in such cases but the other pathologic features are lacking. This has been true in cases of carcinoma (especially of the stomach), pernicious-like anemia of pregnancy, and some refractory anemias.

MICROCYTIC AND NORMOCYTIC ANEMIAS

Insofar as anemias other than the macrocytic anemias are concerned, bone marrow aspiration is rarely diagnostic. The anemias of chronic hemorrhage and of hemolytic disease often show nonspecific normoblastic hyperplasia of varying degree. This can be demonstrated in both spreads and sections of marrow. Aspiration of bone marow in these cases is at times helpful in eliminating other diagnoses, but the positive aids in these anemias come chiefly from the history, physical examination, and peripheral blood studies.

There is a group of anemias in which **sections** of bone marrow material have given us more information than do the **spreads** of the same material. Included are the anemias associated with malnutrition, terminal nephritis, and advanced liver disease. In all these instances the sections of marrow show a marked increase in fatty marrow which replaces normal marrow. The marrow hypoplasia may become so marked that only isolated islands of bloodforming tissue can be seen interspersed between large fat globules. Both sections and smears can be stained for the presence of free iron. This procedure, as mentioned in the hematology section, can be extremely helpful in classifying anemias.

Aplastic anemia and myelofibrosis

In these states the bone marrow may become exceedingly hypocellular or almost completely replaced by fibrous connective tissue. Some comment has already been made concerning the relative merits of spreads and sections in these conditions, with the section technic holding the upper hand. If, however, successive dry taps are encountered, surgical trephine should be performed before such a diagnosis is made.

In addition to these idiopathic states, we have encountered variable degrees of bone marrow fibrosis in other conditions. Chronic blood dyscrasias such as leukemia and polycythemia which have received significant amounts of radiation therapy may show a considerable degree of fibrosis. The same is true of Hodgkin's disease treated with radiation or nitrogen mustards. Some metastatic carcinomas show extensive fibrous replacement of bone marrow. We have observed this to be particularly true in cases in which we were able to demonstrate capillaries plugged with tumor cells. In most of our cases of metastatic carcinoma this was not true; normal marrow units were seen alongside large aggregates of tumor cells. A few cases of sarcoidosis and a rare case of widespread tuberculosis showed marked replacement of normal marrow.

POLYCYTHEMIA

In polycythemia vera, there is hyperplasia of all marrow elements which can be quantitatively appraised better in sections than in spreads. Block et al.[851] have used the appearance of sections as a guide for therapy in polycythemia vera. If the marrow sections show marked hyperplasia, they recommend further active radiation therapy, regardless of the peripheral blood values. We have noted an interesting and undescribed phenomenon in polycythemia vera related to the megakaryocytes. These cells show an unusual degree of cytolysis with all the cytoplasm of almost every megakaryocyte showing platelet formation and leaving bare nuclei surrounded by platelets. This phenomenon might account for the thrombocytosis commonly associated with polycythemia vera and has not been observed in the secondary polycythemias.

MALIGNANT LYMPHOMAS

Malignant lymphomas at times may be diagnosed by bone marrow aspiration. For this diagnosis we still prefer biopsy of lymph nodes over bone marrow aspiration because the former will yield a higher return than the latter. Table 277 requires a word of explanation. The 100% diagnosis under sections as compared with only 9.4% positives in spreads represents comparative figures between the 2 technics. We have not found that 100% of lymphosarcomas can be diagnosed by marrow aspiration but that when the diagnosis is made this way, the sections of marrow will show it 10 times as frequently as the spreads. This disparity between the 2 technics is readily comprehensible when one observes numerous sections of such cases.

Lymphosarcoma has a tendency to form **nodules** in bone marrow rather than to be diffusely spread throughout the marrow. The usual picture is that of a central nodule, consisting solely of lymphosarcoma cells, within a marrow unit, the periphery of which consists of normal marrow elements. Not infrequently this peripheral zone shows a marked eosinophilia. Alongside such affected marrow units may be seen perfectly normal units and these generally outnumber the involved areas. In the preparation of spreads from such material, if one does not happen to catch a nodule of lymphosarcoma cells, the diagnosis will be missed. We have the impression that these lymphoid nodules are held together rather compactly and do not spread well. In the spreads in many of these cases, one may encounter a moderate increase in abnormal lymphocytes but only of sufficient degree to arouse suspicion of the diagnosis. A generalization that appears reasonable from our observations is that when there is an increase in abnormal lymphocytes in the peripheral blood, the bone marrow is likely to show a diffuse spread of these cells. This is the pattern of chronic and acute lymphocytic leukemia and of leukosarcoma. As a corollary to this observation, when we see the nodular type of lesion in the bone marrow, abnormal lymphocytes are then rarely seen in the peripheral blood. At times we have observed one type transform into the other, most frequently the nodular type changing into the diffuse type of disease.

A word of caution is in order concerning lymphocytic nodules in bone marrow. Isolated nodules may be seen in normal bone marrows and in our experience are fairly regularly encountered in elderly persons, particularly those with malnutrition. The finding of an isolated lymphocytic nodule, therefore, does not make a diagnosis of lymphosarcoma. We insist on the finding of goodly numbers of such nodules before making this diagnosis. In well-prepared thin sections, it is often possible to identify individual lymphocytes which are abnormal. An increased incidence of mitoses adds further weight to the diagnosis.

We have found bone marrow aspirations helpful in 2 situations in which lymphosarcoma is suspect. By far the largest number has been those patients who have mediastinal or abdominal involvement and no readily accessible peripheral lymphadenopathy. Marrow aspiration in these cases is a much simpler approach to diagnosis than thoracotomy or abdominal exploration. The other situation in which we have found marrow aspiration useful is in determining the extent of involvement of the disease. We have observed patients with lymphosarcoma of the skin, with no significant organ enlargements or lymphadenopathy, who have shown extensive bone marrow involvement. In these cases we have recommended more vigorous therapy than would have been used for the skin lesions themselves. Prognostically, patients with marrow involvement have had a poorer outlook than those without such spread of the disease.

INFECTIONS

The usual response of the bone marrow in acute infection is moderate hyperplasia of the myelocytic elements with a left shift in this series paralleling the shift seen in the peripheral blood. At times this shift may reach the proportions seen in chronic myelocytic leukemia. There are several helpful differential points in the bone marrows of these 2 conditions, as listed in Table 279.

Table 279

	Infection	*Myelocytic leukemia*
Toxic changes in leukocytes	Present	Absent
Monstrosity forms	Absent	Present
Increased basophils	Absent	Often present
Hiatus phenomenon	Absent	Often present
Myeloblasts	Few	Usually plentiful

In the field of chronic infections with specific granuloma lesions, bone marrow studies may make the diagnosis. Brucellosis, tuberculosis, and histoplasmosis are examples. The success in finding these lesions is dependent on the multiplicity of punctures and the vigor with which the search for them is conducted. Obviously, sections of the bone marrow are superior to spreads. Granuloma lesions such as sarcoid belong in the same category.

Spreads may be helpful in finding the organisms of leishmaniasis, histoplasmosis, and toxoplasmosis. Although articles have appeared suggesting bone marrow studies for malarial infestations, we have not found this procedure necessary. After an extensive experience with malaria in the Armed Forces, Agress' recommendation in this search for malaria is thorough knowledge of the thick drop technic. He was not able to find a single instance of malaria in which he could demonstrate the parasites in bone marrow material and not find them as readily in thick drop preparations.

Culture of bone marrow for isolation of certain organisms has been successful in isolated instances such as brucellosis and tuberculosis.

CONTRAINDICATIONS TO MARROW ASPIRATION

Bone marrow aspiration is not indicated until an adequately complete history, physical examination, and peripheral blood studies have been performed and indicate the desirability of the procedure. In adition to the discomfort to the patient, the procedure carries some danger, a few deaths having been reported as a result of bone marrow aspirations. Perhaps the only medical contraindication to bone marrow aspiration is hemophilia in which uncontrollable bleeding may follow the puncture.

TECHNIC OF BONE MARROW INVESTIGATIONS

The first instrument for the examination of bone marrow was made by Wolff[852] in 1903. This examination was performed by trephination of the diaphyses of the tibias of small animals. Human bone marrow of a living subject was first examined by Ghedini[853] in 1908. This method, following the method of Seyfarth, was used by Schilling and Gradwohl for some time, but has been superseded by the relatively simple process of direct sternal puncture instead of trephining as we previously performed this technic. The difficulties incident to an operation such as trephination were removed by Arinkin[854] in 1929. He used a large needle and trocar and punctured the body of the sternum under aseptic conditions, using a local anesthetic.

Gradwohl[855] reported a new instrumentarium for performing sternal puncture. It consists of a 10 ml. Luer-Lok syringe, a cannula and connector with a rubber tubing joint, a bone marrow puncturing instrument with a guard which can be adjusted to fit the depth of the sternal puncture, and an obturator for the latter.

The skin over the sternomanubrial junction is surgically prepared, the usual sterile drapes are applied, and local anesthesia with procaine hydrochloride solution is injected intradermally and subcutaneously and into the periosteum. The instrument for puncture has a handle which permits a firm grasp and allows one to bore through the external lamina of the sternum and enter rapidly the marrow cavity of this bone. The instrument is thrust through the skin at the sternomanubrial junction at right angles to the surface of the sternum. The guard on the shaft of the needle is so adjusted that the instrument cannot possibly be pushed through the sternum into the mediastinal space. After the instrument has well penetrated the sternum, the direction is changed with the point directed upward. At this time, when the bone marrow has been entered, the obturator is removed, the connector and syringe are attached above the handle of the boring instrument, and suction is applied. One obtains in this way a very definite specimen of the bone marrow. It goes without saying, of course, that the entire instrumentarium must be adequately sterilized before use. One may place a small amount of dilute sterile sodium citrate solution in the barrel of the syringe, which slightly dilutes the bone marrow material.

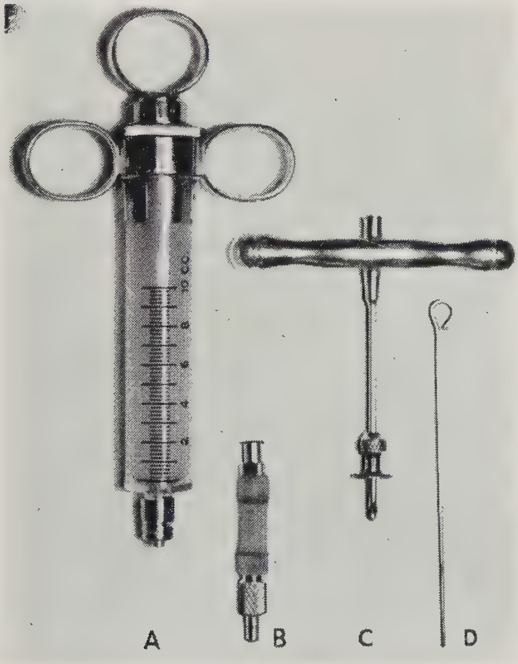

Fig. 464. Gradwohl-Aloe sternal marrow puncture apparatus: **A,** syringe; **B,** cannula and connecting tubing; **C,** bone marrow puncture instrument; **D,** obturator.

The large caliber of the instrument permits one to obtain sufficient bone marrow easily. Once the marrow is obtained, the instrument is rapidly removed, and the opening is closed with a surgical dressing. Repeated punctures on the same patient can be made with this instrument without any difficulty.

It is not necessary to remove a large quantity of bone marrow. Only a small amount is obtained, usually about 0.2-0.3 ml.

Fig. 464 shows the entire setup for the procedure.

Biopsies of sternum—Turkel technic

The Turkel trephine biopsy method[856-863] eliminates the 2 common objections to marrow biopsies: (1) that biopsy is a surgical procedure and (2) that biopsy leaves a disfiguring scar.

The advantages of this method are that it is easily and rapidly performed at the bedside or in the office and does not leave a disfiguring scar. It controls the depth and force of penetration; in other words, it prevents penetration of posterior lamella and mediastinum. There is no dilution of bone marrow with circulating blood. There is preservation of bone marrow topography. Biopsy by this method shows cells adherent to the marrow wall which are not seen by aspiration. Further the biopsy shows the true proportion of cells in the bone marrow or the myeloid-erythroblast ratio. It checks results of treatments quantitatively. It possesses the advantage that aspiration and infusion may be performed through the same aperture.

Procedure:

1. Cleanse the skin over the desired site, usually opposite the third rib, with surgical antiseptic. Infiltrate skin, subcutaneous tissue, and periosteum with local anesthetic.
2. Insert outer needle with stylet in place (Fig. 466) with the tip of the needle in the direction of the face of the patient at an angle of about 45° through the skin, subcutaneous tissue, and periosteum until the tip just engages the anterior lamella of the sternum.
3. Leave the outer needle in place and remove the stylet.

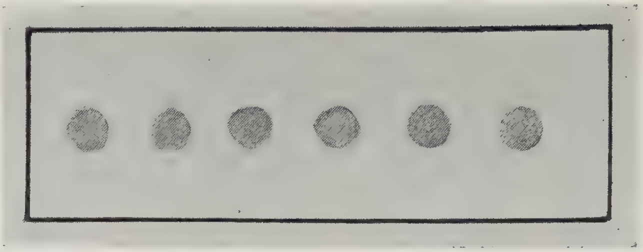

Fig. 465. Bone marrow touch preparation.

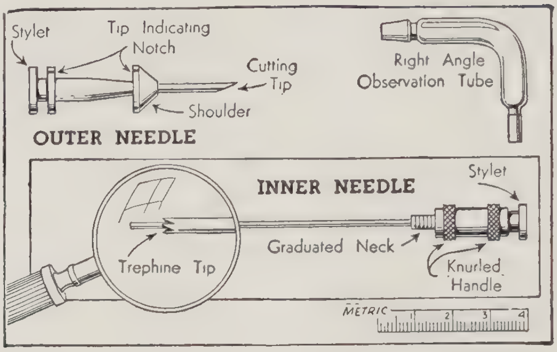

Fig. 466. Turkel needle for aspiration or biopsy of sternum.

4. Insert the trephine needle with stylet into the outer needle.
5. Remove style of inner trephine needle.

While holding the outer needle with the fingers of the left hand, turn the head of the trephine needle with the fingers of the right hand, with a slight clockwise-counterclockwise motion, at the same time exerting gentle inward pressure. A sudden release of resistance signifies entrance of the trephine tip into the sternal cavity. **The clockwise-counterclockwise motion, with slight pressure, should continue until the neck of the inner needle is completely within the head of the outer needle.** Rotate the head of the inner needle in order to detach the plug from the surrounding marrow.

For aspiration:

1. While holding the knurled handle of the inner needle, push the outer needle into the sternum about 6 mm. until the neck of the inner needle becomes completely visible.
2. Remove the inner needle.
3. Attach the syringe and aspirate about 1 ml. blood-marrow mixture.
4. Remove syringe and express mixture immediately into oxalated tube.

For biopsy:

1. Remove the inner needle and with its stylet force the marrow plug into a bottle containing a fixative or use it as imprint or spread.
2. Insert stylet into outer needle, remove outer needle, and cover the point of insertion with antiseptic dressing.

Biopsy of tibia

In infants and younger children it is safer to utilize the tibia instead of the sternum in obtaining bone marrow specimens. Except for the location, the technic is the same as that used in sternal puncture.

Use of iliac crest in bone marrow punctures*

Bone marrow can be obtained easily and safely from the iliac crest and may at times provide information not obtainable from sternal aspiration.

Procedure: The site for the iliac crest puncture is chosen on the crest over an area within 3 cm. posterior to the anterior superior iliac spine on either side of the body. According to the thickness of the tegument a needle 1 to 2½ in. long, 16 gauge, and furnished with a stylet is used for puncture; a 20 ml. tightly fitted dry syringe is used for aspiration.

The determined site is prepared with iodine and alcohol and infiltrated with 2% Novocain solution until the periosteum is reached; the periosteal space is then injected very slowly; usually no more than 2 ml. Novocain solution are required. The patient lies in the supine position; in very pronounced abdominal distention (ascites, enlarged viscera) the patient is tilted on his side. The puncture is performed with the needle held at a 45° angle to the long axis of the body and with pressure applied by the palm of the hand. The aspirating needle is forced into the bone with steady pressure and slight rotation. A distinct give sensation is usually felt when the needle enters the medullary cavity. As the needle is firmly embedded in the medullary cavity, the stylet is withdrawn, and the syringe is attached to the needle. In order to avoid admixture of blood the plunger is slowly withdrawn until the first drop of marrow fluid is observed in the capillary end of the syringe. Bone marrow aspiration is accompanied by a slight sensation of pain (suction pain).

---

*Michael A. Rubinstein, Montefiore Hospital, New York, N. Y. Personal communication based upon facts by Dr. Rubinstein in his Scientific Exhibit, A. M. A. convention, Atlantic City, N. J., June, 1947.

The material removed may be used in the usual way for enumeration of total nucleated cell count, for preparation of smears, and for section study.

The technical advantages of iliac crest versus sternal puncture are as follow:

1. No injury can be sustained by any underlying organ.
2. Usually the iliac puncture is a less painful procedure and the patient is less apprehensive than when subjected to the puncture in the cardiac area.
3. Repeated aspirations of the iliac crest can be easily performed at frequent intervals on both sides; iliac aspiration is very suitable for serial bone marrow studies. This may be important especially in experimental pharmacologic physiologic research of hematologic tissue and bone marrow tumors.

It is suggested that the marrow cavities of the iliac bone can be used as a readily available route of administering fluids into the general circulation when no intravenous route is accessible since they allow for greater safety than the sternal technic.

Disadvantage of the iliac aspiration is the occasional difficulty of puncturing the bone, which at times may prove to be exceedingly firm in this region.

Bone marrow studies were performed simultaneously in iliac crest and sternal aspiration in 216 different cases showing normal and pathologic findings.

Normal: The normal values of the iliac bone marrow were found to be approximately in the same range as those determined for sternal aspiration. Iliac crest counts in hematologically active bone marrow in all age groups of normal individuals studied (age range 16-78 yr.) gave the following results. The total nucleated cell count of the iliac bone marrow, as that of sternal aspiration, tends to decrease with age from the average of 110,000/c.mm. in persons under 20 yr. of age to 50,000/c.mm. in those over 60 yr. of age. The differential count of the normal iliac marrow ranged as follows: myeloblasts, 0.5-2%; promyelocytes, 1-5%; myelocytes, neutrophilic, 11-23%; myelocytes, eosinophilic, 1-3%; myelocytes, basophilic, 0.5-1%; nonsegmented neutrophils, 8-29%; segmented neutrophils, 5-15%; eosinophils, 1-3%; basophils, 0.5-2%; lymphocytes, 2-10%; plasma cells, 0.5-3%; reticulum cells, 0.5-2%; hematogones, 0-3%; proerythroblasts, 0.5-1%; erythroblasts, 2-8%; normoblasts, 10-21%. The number of megakaryocytes ranged between 22 and 88 in 1 c.mm.

Examination of bone marrow preparations

Touch preparations are made on the surfaces of clean fat-free glass slides. A few spreads also are made.

The combination of Wright and Giemsa stain is the best staining method. The specimens are dried in the air and stained with Wright stain 1 min., followed by differentiation in neutral distilled water for 5 min., and then washed. The specimens are then stained for 30 min. with a dilute Giemsa stain made by adding a drop of stock Giemsa stain to each ml. neutral distilled water.

After the staining process is completed, the slide is washed with neutral distilled water, dried in the air, and examined. This combination stain gives excellent results.

In connection with the technic of bone marrow investigations, which was just dedescribed, the method used by Isaacs[864] to count the cells of the bone marrow is of inestimable benefit in the determination of the type of anemia. The description is as follows:

Wet the inside of the tube of a Sahli hemoglobin pipet or the stem of a red or white blood cell counting pipet with serum. The pipet stem should have markings enabling one to measure 4 vol. A serum of the same blood group as the patient is desirable if the red blood cell count is a factor; otherwise any blood serum may be used. The serum is drained out, and bone marrow is sucked up 1 unit of space into the pipet. By working the tip back and forth among the trabeculae of bone, enough marrow may be obtained without air bubbles. Serum is then drawn up so that the total bulk is 4 vol. This is then discharged into a watch glass, using care to wash out all of the marrow. Eight more vol. serum (measured by the markings on the pipet) are then added, and the suspension is stirred thoroughly with a blunt glass rod. This suspension is then drawn into a red blood cell counting pipet to the 0.5 mark and is diluted with Hayem solution or with 1% acetic acid if a count of leukocytes only is desired, the rest of the steps being exactly as in counting red blood cells using a hemacytometer slide.

The high dry objective is used. The total number of cells in 4 or 8 sq.mm. are counted, the adult red blood cells being enumerated in 1 group (if acetic acid has not been used) so that when their number is subtracted from the total, the number of nucleated cells of all types is obtained. The calculations are as follows.

The number of cells counted in 1 sq.mm., obtained by dividing the total number of cells counted by the number of sq.mm. spaces used, is multiplied by 24,000, i.e.:

$$\frac{10 \times 12 \times 200}{\text{No. sq.mm.}}$$

The differential count is made from cover glass films, using a thick emulsion of bone marrow in serum. The fresher the serum, the better are the results. If the serum is of the same blood group, the red blood cells are not agglutinated but are evenly distributed. Human serum may be used for bone marrow of animals. Use Wright or Giemsa stain. When Wright stain is used, allow the stain to act for 1 min. and then dilute with as much distilled water as the cover glass will hold, mixing very thoroughly. Allow this to stand for 10 min., then wash with distilled water, dry, and mount in xylol-balsam.

The most representative bone marrow is obtained from the midsternum, as this gives both red and white cells in the course of their development. This technic may be used with marrow from any bone or for cells of other organs.

With careful technic, the variation in counting cells from the same region in the normal marrow using several pipets averages about 5%, an amount but slightly greater than variations from drop to drop in the same pipet. In pathologic marrows, when there is a grossly uneven distribution of the cells, the variation is considerably greater, amounting to as much as 24% between a cellular and relatively noncellular region and to 85% in marrows with regions of aplasia.

With this method Isaacs maintains that there are from 150,000-300,000 cells/c.mm. in normal sternal bone marrow. He states that the primitive blast stage of the cells of the polymorphonuclear leukocyte series resembles that of the lymphocyte and erythrocyte series of cells in general morphology and may or may not be identical. The next stage in the development of the red blood cell he terms the megaloblast and believes that this is a normal stage in the production of the erythrocyte rather than a pathologic or fetal cell, as many other authorities believe. He calls the next stage in development the basophilic normoblast or macronormoblast. Isaacs calls attention to the variation in the number of cells in the bone marrow dependent upon changes in physiology. In other words, a normal individual may tax his granulopoietic tissue at one time more than another in trying to remain normal. His view of the normal composition of the cells of bone marrow is shown in Table 280.

Table 280

Cell type	*Per cent all nucleated cells*
Undifferentiated lymphoid cells (primitive blasts)	23.1 ± 8.0
Megaloblasts	3.0 ± 1.0
Basophilic normoblasts	7.2 ± 2.5
Eosinophilic normoblasts	12.0 ± 7.0
Polymorphonuclear neutrophils (adult)	7.5 ± 5.5
Polymorphonuclear neutrophils (young)	13.0 ± 6.0
Metamyelocytes	20.8 ± 3.0
Myelocytes	2.8 ± 1.8
Myeloblasts	1.8 ± 0.8
Eosinophils (immature and mature)	5.5 ± 3.0
Lymphocytes	1.0 ± 0.5
Endothelial cells (phagocytes)	0.9 ± 0.5
Hemohistioblasts and hemohistiocytes	2.3 ± 1.3
Megakaryocytes	0.5 ± 0.1
Basophils	Present
Monocytes	Present

He calls attention to the fact that in aplastic anemia the total number of cells per ml. is greatly reduced, and the fat content is increased. So-called idiopathic aplastic anemia differs from aplastic anemia following intensive roentgen ray therapy in that in the latter condition the number of primitive blasts is reduced, but the cells which are present tend to ripen into eosinophilic normoblasts and later into mature erythrocytes. In the hypoplastic anemia of nephritis the inhibition is just after the primitive blast stage so that cells in this stage accumulate in normal or greater than normal numbers, whereas but few ripen to the megaloblast stage.

In pernicious anemia he found that the point of inhibition appears at the megaloblast stage. Inhibition appeared at the normoblast stage in leukemia and infection.

The next stages are eosinophilic normoblast, reticulocyte, polychromatic red blood cell, and the mature erythrocyte.

Agress modification for preparing spreads and sections simultaneously

1. Perform marrow aspiration in the standard manner, using the site of the operator's choice or as indicated in individual problems.
2. Attach a **dry**, sterile, tight-fitting 5-10 ml. syringe to the aspirating needle.
3. Make a **strong, sudden** pull with the plunger, withdrawing only about 0.5-1 ml. of marrow. This first show of marrow generally is the most cellular and has the least dilution with blood.
4. Quickly transfer the entire contents of the syringe to a clean glass slide.
5. Touch this pool of marrow by the edges of successive slides and then spread over individual slides to make the spreads.
6. Generally 8-12 spreads should be made of each preparation.
7. Stain spreads as outlined on p. 1409.

When the pool of marrow has clotted, pick up the clot with the stylus of the aspirating needle, and transfer to a fixative. Thereafter treat like a routine surgical biopsy. Our preference in fixatives is Zenker's acetic acid (10%), which permits the use of special stains if desirable. The routine staining is hematoxylin and eosin, with particular care exercised in differentiation.

Using this method, Agress has found that 92% of spreads and 95% of sections are satisfactory.

Anticoagulants are **not used** at any time in the routine preparation of bone marrow spreads or sections. However, lupus erythematosus (L.E.) cells will only rarely be found when this technic is used. If L.E. cell preparations are desired, the method differs.

For L.E. cells:

1. Leave the aspirating needle in situ.
2. Aspirate 1-3 ml. marrow into a syringe containing a few drops of heparin or other anticoagulant.
3. Allow this material to incubate at 37° C. for 2 hr.
4. Centrifuge at 1000 r.p.m. for 5 min.
5. Make spreads of the buffy coat, and stain (p. 1140) in the routine manner.

For cultures of bone marrow: If cultures of bone marrow are desirable, these too are collected after the routine method has been performed, leaving the aspirating needle in place. A clean sterile syringe containing sterile anticoagulant is reapplied, and an effort is made to obtain as much as 5 ml. marrow material. This is then transferred to appropriate media.

TISSUE CULTURE OF HUMAN BONE MARROW

Osgood has carried out some very interesting research work on cultivation of bone marrow. He has presented this work in various communications.[865-867] This method was used by him for the appraisal of therapeutic agents. It permitted determination of their effect on living human cells, of the toxic dose, and of the minimum therapeutic dose as well as the accurate control of concentration. He showed by his culture method a number of points about the length of life of neutrophils, eosinophils, and basophils of normal blood by comparing blood and sternal bone marrow from healthy persons. The cultures were made in 30 ml. vaccine vials in a medium consisting of about 35% of human cord serum and 65% of the balanced salt solution of the Geys.[868] This medium was previously determined by the Geys to be satifactory for the culture of human tumors. Osgood found it possible to maintain cultures of human marrow in as nearly their natural state as any medium so far investigated.

Method: Assemble the apparatus from 5 two-liter aspiratory bottles,* Pyrex standard wall glass tubing, and pressure tubing. Test its operation. Determine the volume of fluid in bottle 1 at the level of the inlet orifice of 4. Connections must be gas-tight under a pressure of at least 60 in. water. Determine the number of drops/ml. from tips 21 and 11. With water instead of medium flowing through the apparatus at the desired rate for use with the marrow, adjust the temperature of the water bath so that the temperature as determined on the fluid within 1 after a period of time for equilibrium to be reached is 37.5° C., the optimum temperature for the experiment. The temperature in the flask is usually about 1° lower than in the bath, but it should be determined for each experiment. Now disassemble the apparatus at convenient joints. Sterilize bottles 1, 5, and 9 with their connections as far as 23 in the autoclave, wrapping the free ends in paper or gauze. The gas system, including bottles 13 and 19 and their connections, need not be sterile. Reassemble the apparatus using aseptic technic, flaming the ends of glass tubes and pouring 70% alcohol on the rubber tubing before making each connection. Introduce the marrow, obtained as described by Osgood,[869] into bottle 1 through vaccine cap 2.

Introduce medium[869] with syringe and needle through rubber tube 7, previously sterilized with alcohol, into bottle 5. Close screw clamp 8. Force air in through 6 until the medium is all transferred to reservoir bottle. Use compressed air or a blood pressure manometer bulb. Disconnect bulb from 6 and adjust the flow of the medium from reservoir 9 by screw clamp 10, counting the number of drops/min. from tip 11, previously calibrated so that the ml./hr. or 24 hr. can be calculated. Any desired gas mixture can be made up in a spirometer and introduced into bottle 13 by closing screw clamps 14 and 15 and filling bottle 13 completely full with 5 to 10% sulfuric acid.* Attach the outlet of the spirometer to inlet 16 and allow the gas to flow into bottle 13 by opening screw clamps 17 and 18, collecting the acid as it flows out in reservoir bottle 19, which is disconnected for this purpose.

When 13 is almost empty, close 18 and 17, place 19 back on its shelf, and attach to outlet 20. Open 14 and adjust the rate of flow of acid by the number of drops/min. of calibrated tip 21 to give the desired rate of gas flow. Open 15. Filter the gas leaving bottle 13 through sterile cotton 23, pass through trap 24; in passing down tube 3, it equilibrates with the medium flowing through the same tube as it enters culture bottle 1.

Medium[869] and gas enter through fine tip 3. The medium, being slightly cooler than that in the flask, flows across the bottom and then gradually rises to the surface. Pressure of inflowing medium and gas forces the used medium and gas out through tube 4 into reservoir 5, from which the gas escapes through cotton-filled bulb 6. It may be collected if desired.

If desired, tilt culture bottle 1 at any time so that the inlet of 4 is above the level of the liquid. Thoroughly mix by shaking, and aspirate marrow culture through 2 for counts and examination.[869] Calculate total numbers of any cell type present by multiplying the number/c.mm. by vol. culture in c.mm. No semipermeable membrane is necessary because the cells settle out and only the surface layer of fluid flows out through tube 4.

With this method, a rapid, controlled rate of flow of the medium past the cells and a rapid, controlled rate of gas supply is possible. Medium from bottles 1, 9, or 5 may be aspirated with a sterile syringe and needle through the pressure tubing at the outlet at any time for chemical, bacteriologic, or serologic examination. Medium may be used several times by pumping it as described from bottle 5 to bottle 9. Gas may be collected at 6 for analysis.

---

*Any size container may be substituted for these without altering the principle of the method.

*This prevents growth of molds and bacteria and dissolves less carbon dioxide than water.

Table 281. *Azurophil granules*

Diameter cell in relation to lobocyte	*Size of granules*	*Nucleoli*	*Chromatin structure*	*Shape of nucleus*	*Peroxidase stain*	*Name of cell*
Same or smaller	Coarse	Present or absent	Coarse in clumps	Round or oval; sometimes irregular or cloverleaf	Negative	Lymphocyte
Larger	Coarse	Present or absent	Coarse	Round or oval; rarely irregular or cloverleaf	Negative	Prolymphocyte
				Round or oval; rarely horseshoe	Positive	Progranulocyte A (promyelocyte II)
			Very coarse	Round or oval	Negative	Plasmacyte†
		Present	Fine	Round or oval; rarely horseshoe*	Negative	Lymphoblast or granuloblast
	Fine, diffuse	Present	Fine	Round or oval	Negative	Monoblast
				Horseshoe or irregular	Positive or negative	Promonocyte
		Absent	Coarse clumps and strands	Horseshoe or irregular	Positive or negative	Monocyte
Three times as large	Fine, diffuse	Absent	Coarse clumps and strands	Horseshoe or irregular	Negative	Megalokaryocyte

*Rieder cell.

†Cytoplasm opaque; plasma cells with azurophil granules are very rare.

Table 282. *No granules (all have round or oval nuclei)*

Cytoplasm	*Nucleoli*	*Chromatin structure*	*Diameter of nucleus in relation to diameter of cell*	*Size of cell in relation to neutrophil lobocyte*	*Peroxidase stain*	*Name of cell*
Opaque	Absent	Pyknotic	Less than ½	Smaller	Negative	Metakaryocyte*† (normoblast)
		Coarse	Less than ⅔	Smaller	Negative	Karyocyte*† (pronormoblast)
			More than ⅔	Same or larger	Negative	Prokaryocyte* (erythroblast)
			Less than ½	Usually larger	Negative	Plasmacyte†
	Present	Coarse	Less than ½	Usually larger	Negative	Proplasmacyte
		Fine	Less than ⅔	Usually larger	Negative	Plasmablast
			More than ⅔	Same or larger	Negative	Karyoblast* (megaloblast)
Transparent	Present	Fine	More than ½	Usually larger	Negative	Lymphoblast, monoblast, granuloblast (myeloblast)
	Present or absent	Coarse	More than ½	Larger	Positive	Progranulocyte A (promyelocyte II)
					Negative	Prolymphocyte
				Same or smaller	Negative	Lymphocyte

*May or may not contain hemoglobin; other nucleated cells never contain hemoglobin.

†Sometimes two or more nuclei in one cell.

Osgood found that in cultures of human blood by a technic which with marrow permits multiplication, maturation, and functional activity of cells of the granulocyte series for at least 6 wk. the duration of life of the neutrophils averaged 61 hr. and in the majority of instances was between 48 and 90 hr. It seemed probable that these figures represented about the actual duration of life of these cells in the blood. The duration of the life of eosinophils, from 8-12 days, and basophils, from 12-15 days, determined by this method is much longer than the duration of life of the neutrophils.

In Table 281 from Osgood's article are collected the facts regarding the cells with azurophil granules. Table 282 from Osgood's article shows the facts relating to the cells with no granules.

In Table 282 are shown the facts relating to cells with no granules.

Chapter 68

Spleen and liver in hematologic diseases

JOHN D. BAUER

SPLENIC TUMOR AND HEMATOLOGIC DIAGNOSIS

Enlargement of the spleen is quite common. It is important to classify it, if possible, from clinical and hematologic standpoints.

Summary of causes of splenic enlargement

The causes of splenic enlargement may be grouped under the following headings: (1) mechanical obstruction, in other words, venous congestion, (2) infective and toxic conditions, (3) blood diseases, (4) reticuloses and reticuloendothelioses, with or without disturbance of lipoid metabolism, and (5) hemorrhages.

Venous or passive congestion of spleen

This may occur rapidly from failure of the right heart or from thrombosis or thrombophlebitis of splenic or portal veins. It may occur slowly from some central cause such as mitral stenosis or incompetence either alone or associated with changes at the tricuspid orifice, adherent mediastinopericarditis, chronic fibroid myocarditis, emphysema of the lung with chronic bronchitis, interstitial pneumonia, or adherent pleurisy.

Additional **local** causes are (1) cirrhosis of the liver, (2) tumors of the liver, (3) chronic inflammatory thickening along the portal tracts, either syphilitic or tuberculous, (4) pressure upon splenic vein by slowly growing carcinoma of the head of the pancreas, (5) enlarged lymph glands in the hilum of the liver, and (6) aneurysm.

Enlargement due to acute and chronic infective and toxic conditions

Acute infective and toxic conditions produce an enlarged spleen—hyperemic, proliferative, and infiltrative. This acute splenitis on cut section shows the pulp coming off on the knife, the diffluent spleen.

Chronic infective enlargements are due to tropical diseases, malaria and kala-azar, or to syphilis and tuberculosis.

This initial hyperemia is replaced by hyperplasia of the splenic tissue, especially of the pulp, so that the color is frequently paler than normal, the consistency is either normal or a little increased, and the capsule is thickened. Later hyperplasia of the stroma occurs, with thickening of the organ. The sheaths of the vessels and sometimes the trabeculae show hyperplasia of connective tissue. This may cause atrophy of the cellular constituents in the pulp. Cut sections show distinct mottling with lighter and darker red parts. At times there is marked pigmentation, and frequently there is adherent perisplenitis.

Spleen in malaria: There are found acute inflammatory swelling of the spleen and melanin and hematogenous pigment contained in free or fixed phagocytes or lying free in the sinuses. Parasites are found in the red blood cells of the pulp and in the large phagocytes. In chronic malaria, the spleen is harder from an increase of the reticulum, which predominates over the cellular hyperplasia; the color is gray brown.

Spleen in kala-azar: Enlargement is associated with marked anemia, leukopenia, skin hemorrhages, local dropsies, and enlargement of the liver and exceeds enlargement due to malaria. Microscopically many large mononuclear histiocytic phagocytes, 4-5 times the diameter of a red blood corpuscle, are seen containing numerous oval parasites. Other cells of smaller size lying in the pulp contain red blood cells and pigment. In later stages there is considerable increase of the reticulum, especially near the malpighian bodies.

Tuberculosis of spleen: This is secondary, or there may be tubercles from acute miliary tuberculosis or subacute and chronic tubercles with caseation. In children a bovine origin of the infection is suggested.

Spleen in syphilis: In acquired **syphilis** the spleen is enlarged, especially in the tertiary stage, with waxy or amyloid infiltration. In congenital syphilis in children enlargement is associated with recent or old perisplenitis, accompanied by diffuse fibrosis, endarteritis, and occasionally periarteritis, numerous spirochetes can be demonstrated.

An increase of the reticulum is seen in Hansen's disease, with enlargement, perisplenitis, atrophy of malpighian bodies, and disappearance of lymphocytes. There are numerous leprous cells in clusters.

Splenic enlargements in blood diseases

The spleen is usually greatly enlarged in chronic myelogenous and lymphatic leukemia, in polycythemia and erythremia, in hypersplenism (splenic anemia), and in congenital spherocytosis and thrombocytopenic purpura. Moderate splenomegaly may be seen in hemolytic anemias, pernicious anemia, acute leukemias, infectious mononucleosis, and lymphomas.

Splenomegalies in reticuloses and reticuloendothelioses

This includes active hyperplasia of the true reticulum, with changes in follicles of lymph glands and in malpighian bodies of the spleen. In reticuloses the spleen may weigh as much as 4.7 kg. Red pulp is described with large malpighian bodies, the ordinary lymphocyte being crowded out. Large cells are seen.

Spleen in Hodgkin's disease: Enlargement is uniform, and the capsule is thickened. Section shows congestion and is a brownish red color; malpighian bodies are prominent. There is an accompanying alteration of the lymph glands of the body. Reed-Sternberg cells with nongranular cytoplasm and convoluted, indented, or ring-shaped nuclei, closely resembling the giant cells of bone marrow, are present. Eosinophils are present.

Reticuloses associated with disturbance of lipoid metabolism

Gaucher's disease: The spleen may weigh from 3000-4000 gm. Pulp is infiltrated with Gaucher cells. In the consideration of Gaucher's disease, one must bear in mind that it belongs to the diseases known as xanthomatosis or a series of clinical and anatomic conditions in which lipoid substances are deposited in certain tissue systems or organs of the body. Xanthomatoses have been classified as generalized or local.

There are 2 generalized types—symptomatic and essential or primary.

The symptomatic form is seen as multiple xanthomas in diabetes or liver diseases which are associated with jaundice and also in chronic kidney disease. These xanthomas occur as yellow pealike nodules in the skin. Lipid is deposited in proliferating cells of the connective tissue of the skin and in the endothelium of lymph vessels. These large cells contain fat.

The second type of the generalized form, the essential or primary xanthomatoses, comprises Gaucher's disease, Niemann-Pick disease, Hand-Schüller-Christian disease, and the primary nonsymptomatic external and internal xanthomatoses in the skin and inner organs.

Gaucher's disease was first described by Gaucher in 1882. He called it a primary epithelioma of the spleen. In 1900 Bovaird of New York called it a nonneoplastic disease, stating that it was endothelial hyperplasia in the spleen, liver, and lymph nodes. In 1907 Schlagenhaufer called it a systematic affection of the reticulum cells of all lymphatic and hematopoietic organs, including the bone marrow. In 1907 Marchand recognized the importance of the deposit of foreign substances in the histogenesis of the Gaucher cells. In 1916, Mandelbaum and Downey found conception of the origin of these cells. In 1924, Lieb and Epstein by study of the spleen showed the lipoid nature of the Gaucher substance, showing that kerasin is its important constituent. Kerasin belongs to the cerebrosides (sphingogalactides). This disease is not rare. Pick in 1926 collected 39 cases to that date. Cushing and Stout in the same year collected 50 cases in the United States. Hoffman and Makler[870] collected 80 cases in all, including their own case.

The disease is of familial incidence. Collier first reported its occurrence in more than one member of a family. It is more common in the female.

It is characterized by splenic and liver tumors. The oldest patient of Pick was 56 yr. The bone was involved as noted by pain in the lower ends of the femur and tibia or tenderness over the sternum and ribs. The earliest signs are the characteristic pigmentation of the skin and definite blood changes. The skin pigmentation, confined mostly to the face, neck, and hands, is yellow brown to ochre. There also occur brownish yellow wedge-shaped thickenings of the sclerae, the base of the wedge lying toward the margin of the cornea.

Pathologic anatomy: A very large spleen weighing as much as 8100 gm. is characteristic. Cut section shows a reddish gray, pink, or sometimes chocolate-brown background stippled with innumerable gray-white or gray-yellow markings, corresponding to accumulations of Gaucher cells. Small or large nodular cavernous foci form in the spleen and are always multiple. The liver may weigh 3300 gm. Remember, the normal weight is about 1500 gm.

The lymph nodes show no enlargement of the superficial glands, but enlargement and pigmentation of the intrathoracic and intra-abdominal glands occur.

The essential histologic change is the presence of many Gaucher cells which are demonstrable by acid fuchsin stain after picric acid fixation. The cytoplasm is wrinkled, giving a vacuolated appearance. There are arterial branches within the nests of Gaucher cells. Pigment is absent only in children and infants. Because of the disappearance of Gaucher cells, we see fibrotic nodules. In the liver the process is cirrhotic and contains nests of Gaucher cells.

The peculiar appearance of Gaucher cells is due to the presence of kerasin, which may be demonstrated chemically even in dried spleens. The formula of kerasin given by Rosenheim is $C_{47}H_{91}NO_8H_2O$. It has properties similar to phrenosin and accompanies phrenosin in tissues of the nervous system, both constituting a cerebroside or glycolipin. Capper et al.[871] report a case of Gaucher's disease with presentation of a table differentiating the lipoid disturbances, as shown in Table 283.

Method for demonstration of kerasin (Bloom and Kern[872]) is carried out by taking formaldehyde-fixed spleen or fresh spleen, grinding through a meat chopper, and drying to a constant weight in a vacuum desiccator. The dried powder is then extracted for 5 days with ether in a Soxhlet. The residue is extracted with ethyl alcohol at 40° C. for 36 hr. The material is further extracted at boiling temperature in a fresh portion of ethyl alcohol for 5 days. The ether soluble fraction is treated with acetone, the resulting precipitate of phosphatids is filtered off, washed with acetone, and dried to constant weight in the vacuum desiccator. The acetone and ether are removed from the filtrate, and the residue, containing cholesterol and fatty acids, is dried to constant weight.

That part of the precipitate from the 40° C. alcohol fraction is dissolved in 100 ml. alcohol to which are added 30 ml. cold saturated mercuric chloride. This gives a colorless gelatinous precipitate, much like egg white in appearance, which fills the entire solution. The precipitate is removed by filtration and is suspended in methyl alcohol; hydrogen sulfide is passed through the suspension. The precipitate is filtered off, the filtrate is boiled with charcoal, and is filtered again. This filtrate when concentrated and cooled gives an almost white gelatinous precipitate. Under the microscope this appears as round crystals arranged radially about a nucleus. On hydrolysis of the material for 8 hr. in methyl alcohol and sulfuric acid under a reflux condenser a white crystalline material with a melting point of 56.7° C. is obtained, which corresponds very closely to that of the methyl ester of lignoceric acid.

It is interesting to note that Gaucher cells arise from the endothelium of blood vessels. Gaucher's disease is evidently a primary disease of the reticuloendothelial system, based upon an error in metabolism. The pigmentation is due to the fact that lipid-storing cells of every sort show a tendency to store simultaneously hemoglobinogenic pigments; with stimulation of the reticuloendothelial structures. The mild anemia which is constant in this disease is due to the bone marrow penetration by the Gaucher cells.

The bony changes are demonstrable by roentgenologic examination.

Hematologic findings: The **blood changes** are leukopenia, which may be due to diminution of neutrophils or lymphocytes, moderate hypochromic anemia, often thrombocytopenia, and often bleeding from the nose or gums, hematemesis, melena, or uterine bleeding. Even slightest trauma produces purpuric bleeding. Bone marrow puncture shows a Gaucher type of cell.

Death is not usually due to cachexia but more often to an intercurrent disease, such as pneumonia, sepsis, tuberculosis, or carcinoma. Some of these patients die following splenectomy.

Niemann-Pick disease: Niemann-Pick disease is found in children, especially females, but in contrast to Gaucher's disease its course is rapid and leads to death within 3 yr. Lipoids are found in the spleen. Scar formation in the later stages replaces the lipoid formations. These changes must be distinguished from those occurring in familial amaurotic idiocy, known as Tay-Sachs disease, which may occur simultaneously. The visceral changes in Niemann-Pick disease do

Table 283. *Xanthomatoses or lipoidoses—diseases due to disturbances in lipoid metabolism**

Name	*Type of lipid*	*Blood findings*	*Eyegrounds*	*Spleen, liver, and glands*	*Age*
Gaucher's disease (90-100 cases)	Cerebroside (kerasin A sphingogalactid)	Hypochromic anemia Leukopenia Thrombopenia Later, hemorrhagic diathesis	Negative	Spleen markedly enlarged Liver enlarged Slight or no lymphadenopathy	Infancy to adult life
Niemann-Pick disease or lipoid histiocytosis (Bloom)	Phosphatids	Moderate secondary anemia Slight leukocytosis Vacuolization of nongranulated cells Excess of lipids in blood	Cherry-red spot in macula lutea *occasionally* found	Spleen and liver very large Moderate lymphadenopathy	Infancy
Hand-Schüller-Christian disease (45-50 cases)	Cholesterol and its esters	May be hypercholesterolemia	Negative	Not enlarged	Any age
Tay-Sachs disease or familial amaurotic idiocy	A prelipid	Negative	Cherry-red spot in macula lutea *usually* found	Usually negative	Infancy
Xanthomatoses of skin, etc.	Cholesterol and its esters	Negative	Negative	Negative	Any age

*From Capper, A., Epstein, H., and Schless, R. A.: Am. J. M. Sc. **188**:84, 1934.

not occur in Tay-Sachs disease, nor do all cases of Niemann-Pick disease show the cerebral changes of Tay-Sachs disease, in which the brain is hard and leathery, the fissures are widened, the corpus callosum is atrophied, and fat granule cells collect about the blood vessels.

This disease is similar to Gaucher's disease from a histologic standpoint. It is a typical disturbance of the histiocyte apparatus. There is great enlargement of the liver, a change which occurs much more rapidly than it does in Gaucher's disease.

The blood picture is similar to that of Gaucher's disease.

Anatomically, Niemann-Pick disease differs from Gaucher's disease in that the characteristic cells are much more prevalent in the spleen, liver, lymph glands, and bone marrow. Reuben maintains that the anemia of Niemann-Pick disease is not as severe as that of Gaucher's disease, nor is the leukopenia as pronounced. He also states that the qualitative leukocytic blood picture is unchanged. Moschokowitz reported a case with 33% hemoglobin, 1,600,000 red cells, and 6500 white cells, of which 90% were neutrophils. According to Reuben the prognosis in children is more severe than in adults, and it is a more rapidly fatal disease. It seems to be associated with delayed development of the blood.

Xanthogranulomatosis: Xanthogranulomatosis is also known as the Hand-Schüller-Christian disease. This disease attacks males and is often associated with exophthalmos and diabetes insipidus. Deposits of cholesterol esters within large phagocytic cells fill multiple defects in the skull; there are also deposits in the white matter of the brain and cord, in the periosteum of other bones, and in the lungs, pleura, liver, lymph glands, bone marrow, and spleen.

Banti's disease: The term splenic anemia does not refer to any specific disease; it is simply a term used to describe those cases with both enlargement of the spleen and anemia.

Splenic enlargement may occur in the following conditions: (1) anemias, (2) hemorrhagic diatheses, (3) polycythemia, (4) lymphatic leukemia or lymphogranuloma, (5) myelocytic leukemia or aleukic myeloses, (6)

Bones	*Pathognomonic features*	*Skin*	*Treatment*	*Remarks*
Mottling and rarefaction with cortical thinning; flasklike appearance ends of femora	X-ray appearance of long bones, especially femora Splenic puncture Bone-marrow examination	Subicteric pigmentation of exposed parts in 45%; yellow thickened pingueculae in eyes in 15%	Splenectomy (fatal in 20%) or radiation (both palliative)	Common in Jews
Any bones or organs may be invaded by foam cells	Splenic puncture	Brownish yellow discoloration	No treatment; all fatal	Mental retardation may be present resembling Tay-Sachs disease; most common in Jews
Membranous bones involved	Defects in membranous bones Diabetes insipidus Exophthalmos Gingivitis and stomatitis Adiposogenital dystrophy	Negative	X-ray treatment of involved area causes prompt local healing but does not stop the progress of disease	
Not involved	Eyegrounds Mental retardation Hyperacusis	Negative	All fatal	Brain shows prelipid deposits in granular layer and about dendrites of Purkinje cells; most common in Jews
Any bones may be involved		Xanthomatoses of any part of skin	Excision if tumorous	

chronic infections such as congenital syphilis, malaria, leishmaniasis, etc., (7) rickets in first year of life; later it disappears, (8) acute infections such as typhoid fever, miliary tuberculosis, and septic infections, (9) Gaucher's disease and Niemann-Pick disease, (10) localized splenic tuberculosis, (11) Banti's disease in which there is fibrosis of the spleen, liver cirrhosis, and finally anemia, (12) splenic tumors from circulatory disturbances such as cardiac stagnation in beginning heart failure, beginning heart failure from valvular disease, stagnation from acute or chronic thrombosis in the venae cavae, or through stagnation by reason of pericardial adhesions, and (13) splenic tumor in liver cirrhosis.

Banti's disease is accompanied by enlargement of the spleen without any change in the lymphatic glands, followed by symptoms of simple anemia and by weakness, dyspnea, etc. Hemoglobin content may drop to 30%. There follows a second period during which the liver enlarges without icterus and without ascites, but the splenomegalia remains. This lasts perhaps for 8-13 mo. The third period is accompanied by ascites and decrease in the size of the liver. There is atrophic cirrhosis in the liver. It occurs after hemorrhages or through the progressive liver atrophy. The number of red cells is not markedly decreased, but the color index is lower. Nucleated red cells are not seen. The lymphocytes are usually decreased. Histologic investigation of the organs in fatal cases of Banti's disease show fibroadenosis of the spleen, including the pulp as well as the follicles. In the second stage of the disease there is a sclerotic condition of the intrahepatic veins and later hypertrophy of the interstitial material. No siderosis is seen in the liver.

Blood picture: There is marked and constant leukopenia; sometimes the white cells are decreased to as low as 1000/c.mm. There is no change in the differential picture. As noted previously, the anemia progresses with the advance in the disease. There is a low color index. There may be as few as 3,000,000 red cells/c.mm. with 40% hemoglobin. Hemorrhages into the stomach are followed by further reduction in the red cells and hemoglobin percentage, together with temporary posthemorrhagic leukocytosis. The anemia itself may be severe enough to be fatal. There is an increased resistance of the red cells to hemolysis in hypotonic salt solution.

Splenomegaly in presence of hemorrhages

This enlargement and the edematous softening of the spleen occur whenever there have been blood effusions and hemorrhages of any considerable size in any organ or cavity of the body. It is due to increased function or blood destruction in the main.

Tumors of spleen

Primary fibroma, chondroma, osteoma, lymphangioma, hemangioma, and melanoma of the spleen have been recorded. Of secondary tumors, sarcomas occur less infrequently than carcinomas. The most common type is melanotic sarcoma.

Animal parasites

Most frequent are the hydatids of *Echinococcus granulosus.*

Cysts

Cysts of the spleen are rare. True cysts come from dilatation of blood spaces, cavernous angioma, or dermoids, or they may be parasitic. False cysts may be traumatic due to necrosis with softening, or tuberculous.

Abscess

Abscess of the spleen is seen in sepsis.

SPLENIC PUNCTURE[873]

Splenic puncture requires withdrawal of splenic pulp without blood. Use an oxidation-proof needle of steel or nickel 8-10 mm. diameter and an absolutely air-tight syringe.

Produce superficial anesthesia by means of an intracutaneous Novocain wheal. Insert the needle into the superficial muscular plane strictly in the zone of splenic dullness, immobilize the patient by asking him to hold his breath, give a short, but decided thrust, and rapidly and energetically aspirate, permitting the piston to return into its position of rest before the needle is withdrawn. The patient remains in bed for 12-24 hr. Ice is constantly applied to the splenic region to prevent internal hemorrhage.

Splenograms are made by staining according to Wright-Giemsa (p. 1143), studying the aspect of the red cells and the relative number of hematoblasts. The normal percentages are given in Table 284.

The splenogram shows closer and more numerous cells than the corresponding hemogram. Abnormal erythrocytes are lacking. Platelets are present in larger numbers than in the peripheral blood. Determination of their number and coloration is one of the chief elements of splenic puncture.

Table 284. *Splenogram*

Neutrophilic polynuclear cells	20-30%
Eosinophilic polynuclear cells	1%
Basophilic polynuclear cells	Rare
Typical lymphocytes	50-60%
Medium mononuclear cells	10-20%
Monocytes	5-10%
Plasmacytes	1- 2%
Normoblasts	20%
Naked nuclei	Numerous

Background, thick, sometimes granular; erythrocytes, normal; platelets, very numerous.

Typical splenograms for each of the various pathologic reactions of the spleen are as follows.

Lymphomatosis: The splenogram of the lymphocytic leukemias is remarkable for homogeneity, achieved by the abundance of white elements, expressing the hyperplasia. Adult and young lymphocytes stand out from a clear and also homogeneous background. The young lymphocytes are much more numerous than in a normal splenogram (30-50% instead of 0.5-3%); however, the presence of all intermediary ages between a lymphoblast and a lymphocyte makes it difficult to perform an accurate count. Polynuclear monocytes and plasmacytes and especially normoblasts and megaloblasts are scarce, the latter even exceptional.

The uniformity and constancy of the microscopic appearance of material obtained by splenic puncture in the lymphomatous diseases are a powerful argument for uniting forms apparently so far from each other as lymphocytic leukemias and pure splenic lymphomas.

Myelomatosis: The splenogram of the myelomatoses is marked by a variegated aspect which is due to the great changes of the elements of the myeloid series under the influence of age and also to the more or less marked, but always noticeable, prevalence of a normomegaloblastic, exceptionally megakaryocytic reaction. This notwithstanding, the myelomatous splenogram is a distinct and isolated type. The characteristic cells abound: myelocytes of all ages and all sizes, metamyelocytes, promyelocytes, primitive cells, hemohistioblasts, hemocytoblasts, polynuclears, and erythroblasts. The background is thick and granular, containing numerous platelets and poorly colored red blood cells.

Leukoblastoses: The splenogram of acute leukemia shows a marked prevalence of the typical primitive cells (90-95%). The other cells are more mature yet decidedly young. These elements permit tracing of the origin of the affection—lymphomatosis, myelomatosis, or erythroblastomatosis.

Cryptoleukemias: A new chapter on leukemias, namely, one on atypical leukemias and cryptoleukemias (aleukemias or subleukemia) was written in terms of splenic puncture. These conditions were not capable of diagnosis by the ordinary methods of investigation. Whether or not the peripheral blood shows abnormal elements, the splenogram shows atypical young cells.

RELATIONSHIP OF LIVER TO BLOOD DISORDERS[874]

The liver participates in blood disorders by virtue of its function as a reticuloendothelial organ, its role in the metabolism of blood pigments, in the storage of iron, in the synthesis of blood proteins, and in the storage of the antipernicious anemia factor. Furthermore the spleen, which participates in so many blood dyscrasias, bears an intimate relationship to the liver both physiologically and pathologically.

In most blood dyscrasias the liver is affected to some extent, and it may be markedly enlarged. However liver function is seldom significantly impaired. Green and Conner in 1926 and other investigators since then have shown that all of the commonly used liver function tests usually give normal results in hepatomegaly due to leukemia, polycythemia, hemolytic jaundice, pernicious anemia, and even Gaucher's disease. In polycythemia the liver is frequently enlarged due to chronic hyperemia, in leukemia there may be marked infiltration of the liver with leukemic cells, in pernicious anemia the hepatomegaly which is sometimes seen is due to fatty changes and hemosiderin deposits, whereas in Gaucher's disease, Hodgkin's disease, lymphosarcoma, and several other diseases of the reticuloendothelial system striking pathologic changes may be found in the liver. The fact that these diseases rarely result in any significant impairment of liver function either clinically or by laboratory testing is a manifestation of the great reserve power of the liver.

Jaundice is common in the blood dyscrasias, and this sometimes leads to an incorrect diagnosis of primary hepatic or biliary tract disease. In congenital or acquired hemolytic icterus, the jaundice is obviously due to the rapid breakdown of red blood cells either as a result of an inherent fragility of the erythrocytes or possibly due to the action of a hemolysin. In pernicious anemia the characteristic lemon yellow color is due to either an abnormality of pigment metabolism or hemolysis.

Rich and associates have suggested that in any hemolytic anemia the jaundice may be due to a combination of rapid disintegration of erythrocytes with a hepatic lesion. It is very difficult to produce jaundice in a dog by the injection of bilirubin. Furthermore, Rich showed that simple hemorrhage in dogs as well as pernicious anemia and secondary anemias in human beings may be accompanied by damage to the cells around the efferent veins of the liver lobules. This lesion is identical with that seen in chronic passive congestion of the liver, and Rich postulated that the lesion is due to tissue anoxia resulting from the anemia. The jaundice is thus due to a combination of hemolysis plus functional liver damage. In human hemolytic anemias a hepatic lesion is not always demonstrable histologically, but it is probably true that a perfectly normal liver can excrete all the bilirubin the body is capable of producing; hemolysis alone, therefore, probably cannot produce jaundice unless the liver is functionally deranged.

In leukemia, as well as in the so-called lymphomas, mild jaundice sometimes occurs due to infiltration of the liver or destruction of liver cells by the lymphomatous process. Occasionally enlarged lymph nodes in the portal fissure may occlude the bile ducts and produce marked jaundice. Jaundice due to this mechanism may be completely relieved by x-ray therapy directed to the upper abdomen.

Hemorrhagic disorders due to diseases of liver or biliary tract: In any hemorrhagic disease there is always a defect of either capillary permeability or the coagulation mechanism. So far as is known, the liver has nothing to do with capillary permeability, but the liver does contribute to blood coagulation. There are 4 essential substances which must be present in order for blood to coagulate normally: thromboplastin, Ca ions, prothrombin, and fibrinogen. Of these, fibrinogen is probably synthesized solely in the liver, whereas prothrombin is synthesized primarily in the liver. Thus theoretically liver disease may result in hemorrhage due to failure of synthesis of either of these factors.

Actually, a condition known as **congenital fibrinogenopenia** has been described in which there is a specific congenital defect in the ability of the liver to synthesize fibrinogen; however, only half a dozen cases have been described. The amount of fibrinogen normally present in the plasma is far in excess of what is required for coagulation. In any kind of severe liver disease, the plasma fibrinogen level may be decreased below normal, but this is always overshadowed by the much more marked and more significant decrease in prothrombin.

One of the factors that may produce bleeding due to **inadequate amount of prothrombin in the blood is vitamin K deficiency.** Dietary deficiency never produces vitamin K deficiency in adult human beings, as proteolytic bacteria in the intestines can synthesize all the vitamin K that is required. However during the first few days of life there are few if any bacteria in the intestines, and in the newborn infant prothrombin deficiency is common. This is generally accepted as being the principal factor responsible for hemorrhagic disease of the newborn.

In adults, vitamin K deficiency occurs only when there is poor absorption from the intestinal tract due to either severe diarrhea or absence of bile salts in the gut. Vitamin K is fat soluble and is not absorbed in the absence of bile salts. Thus, the bleeding which occurs in severe obstructive jaundice can be corrected either by the parenteral administration of vitamin K or by the administration of bile salts by mouth.

In contrast to this type of prothrombin deficiency, the **prothrombin deficiency resulting from severe liver damage** is not affected by vitamin K administration. When the liver cells which synthesize prothrombin are destroyed, the only rational therapeutic approach is to keep the patient alive by supplying prothrombin from without in the form of plasma transfusions. This stops the bleeding only temporarily but is an extremely important procedure whenever the nature of the liver disease is such that regeneration of liver tissue is possible.

A condition known as **congenital hypoprothrombinemia** has been observed in a few children in which the liver lacks the ability to synthesize prothrombin. There have been very few cases of this sort reported in the literature, but now that it is being looked for, it is being recognized more frequently. Quick stated that he has knowledge of over half a dozen such cases himself.

Role played by liver in certain anemias: The liver plays an important part in 2 types of anemia—pernicious anemia and iron-deficiency anemia. It is well established that erythrocyte maturation factor is stored in the liver, and the liver of patients with pernicious anemia lacks this substance. It has been shown that cirrhotic livers are deficient in erythrocyte maturation factor. It is, therefore, very easy to assume that the anemia so commonly seen in various types of liver disease is due merely to the absence or diminished quantity of this factor in the liver.

It is known that some degree of anemia is usually present in advanced cirrhosis of the liver. But perhaps sufficient emphasis has not been placed on the fact that in only about half of these cases is the anemia macrocytic. The mean corpuscular volume in general is in the vicinity of 100 c.μ; however, the macrocytosis does seem to increase as the anemia becomes more marked. The anemia of cirrhosis is often accompanied by reticulocytosis and occasionally by mild leukopenia. It has frequently been suggested that because of the close resemblance of the blood picture to that of pernicious anemia, the damaged liver is responsible for a deficiency of antipernicious anemia factor. A reticulocyte response to the administration of liver extract does occur in some of these cases, but in other cases of cirrhosis no such effect is obtained. It is probable that the anemia of cirrhosis and other types of severe liver disease is not due to deficiency of erythrocyte maturation factor.

It is important to remember that macrocytosis which is so characteristic of pernicious anemia also occurs in the anemias of chronic uremia and occasionally in leukemia. Furthermore in normal animals the kidney as well as the liver contains large amounts of antipernicious anemia factor, and thus it is hard to see how liver disease alone could produce a significant decrease in the amount of available erythrocyte maturation factor unless the kidneys were simultaneously damaged.

Castle studied the macrocytic anemias due to nutritional deficiency. In 2 of the 3 patients he studied, the anemia developed during pregnancy. In spite of the fact that the anemias in all 3 of these patients were strikingly macrocytic, no reticulocyte response occurred in any of them following the intramuscular injection of liver extract. In all 3 cases, however, a reticulocyte response followed by a gradual rise in red blood cell counts occurred when liver extract was given by mouth. Castle concluded that the "unitarian" hypothesis which regards all macrocytic anemias as being due to deficiency of erythrocyte maturation factor is not tenable. He suggested that in this type of nutritional macrocytic anemia the digestive organs form a new hematopoietic substance from the liver extract in a fashion analogous to the food-gastric factor relationship in true addisonian pernicious anemia. Present evidence does not justify the conclusion that all macrocytic anemias are due to the same mechanism; there is no conclusive proof that the macrocytic anemia of liver disease is due to deficiency of antipernicious anemia factor.

When red blood cells are hemolyzed in the body, the hemoglobin is broken down, and the iron thus liberated is stored in the reticuloendothelial tissues throughout the body. The liver is perhaps the most important of all the organs which store iron. By virtue of this storage mechanism, extremely minute quantities of iron are lost from the body by excretion. It is for this reason that hypochromic microcytic anemia due to iron deficiency practically never occurs except in hemorrhagic states in which large amounts of actual hemoglobin are lost from the body. Hypochromic microcytic anemia due to iron deficiency very rarely if ever occurs as a result of inadequate intake of iron in the diet. Thus the liver plays an important part in iron metabolism.

Chapter 69

Hematology of infants and children

JOHN D. BAUER

Since blood pictures in infants and children normally differ somewhat from those in adults, we shall give briefly the salient differences so that proper interpretation of findings may be made.

At birth the number of white cells is very high, around 30,000, and declines to normal after the first week. It is also interesting to note that there is a left shift during the first week of life. The count of the blood platelets is also variable during the first week, sometimes reaching very high proportions.

The percentage of hemoglobin in blood at birth is very high, figures as high as 130% having been obtained. Hemoglobin falls soon after birth, reaching normal around the end of the first week.

The number of red cells is very high at birth, beginning to fall on the third day after birth.

At birth the presence of nucleated red cells in the film has no pathologic significance. The same is true of the great prevalence of reticulocytes and polychromatic cells. Anisocytosis is common and not pathologic.

One must divide these young subjects into 3 groups in order to get a proper estimation of hematologic data: newborn babies, nursing infants, and infants from 1-6 yr. of age. The average adult blood picture is not reached before the sixth year, but even then and sometimes later lymphatic reactions are produced much more easily than in the adult and wide fluctuations are commonly seen. In general, the blood picture at birth is markedly neutrophilic and shows a great shift to the left. Physiologic myelocytes and juvenile cells have been seen at this time under perfectly normal conditions. The neutrophilia with marked shift, as Arneth says, represents pathologic leukocytosis of the birth process. It is very probable that the accommodation of the body to the new circulation and respiration irritates the residue of embryonal blood forms and liberates them into the blood stream. Lymphocytes increase rapidly in the relative picture.

The blood pictures of prematurely born babies exhibit greater abnormalities than those of normally born children; i.e., their blood pictures may closely approximate the embryonal blood picture. Prematurely born children at first show high leukocytosis and neutrophilia. This recedes, together with the marked nuclear shift.

BLOOD PICTURE OF NURSING INFANTS

The blood picture of the nursling remains constant in the first year and up to the middle of the second year. At this time it begins to change gradually into an appearance like that of the blood of the adult, finally attaining this adult appearance about the sixth year. There is still high **lymphocytosis.** The number of neutrophils in the nursing child is about 25-30%, and the lymphocytes are from 42.5-90.5%, according to Hofmann and Welker. Gundobin considers the following the average for nurslings: neutrophils, 34.6%; lymphocytes, 59%; monocytes, 6.4%.

Morphology of blood in infancy

There is an extreme lability of the blood-forming apparatus in early infancy; i.e., it is much more sensitive to irritation than that of the older individual.

Table 285. *Blood picture in nurslings ages 1-12 mo.**

No. cases	Age (mo.)	Hemoglobin (%)	Red cell count (c.mm.; millions)	White cell count (c.mm.)	Neutrophils (%)	Eosinophil (%)	Basophil (%)	Lymphocyte (%)	Monocyte (%)	Metamyelocyte (%)

*From Carstanjen: Jahrb. f. Kinderhk. **52**:1900.

Many authorities have noted the high percentage of hemoglobin and increase of cell count at birth. These figures fall rapidly after the first few days. Perlin noted a drop in hemoglobin after the fourth day with a gradual decrease, reaching its minimum at the end of the first year, namely, 58-78%. From the second year on it begins to rise, up to the fifteenth or sixteenth year of life.

The count of the red cells drops soon after birth. Toward the end of the first year it is at its lowest point, namely, 4,200,000, when the count begins to rise, up to the end of the fourth year.

Williamson and Appleton[875] give the figures shown in Table 286.

One must be careful in infancy cases in drawing conclusions from the shift of the neutrophils for the reason that 1.5% juvenile cells and 18% stab cells as well as an occasional myelocyte have been found in healthy infants. This is due to the remarkable lability of the hematopoietic apparatus in infancy. **The hemogram of Schilling is useful in infancy but**

not from a single examination. Conclusions must be drawn only from repeated examinations.

The number of blood platelets in infancy varies greatly. The average count is between 200,000 and 300,000. McClanahan and Mitarbeiter[876] in a report on 68 blood examinations in infancy gave the figures shown in Table 290 on blood platelets.

The hemoglobin content of the blood of children from 1-10 yr. of age is seen in Table 287.

Sedimentation phenomenon of the red cells in infancy is different from that in adults. In the Linzenmeier test in adult females, sedimentation drops to 18 mm. in 800-1000 min. and in males in 1200-1400 min. In newborn babies, the sedimentation rate of 18 mm. occurs in from 6-7 hr., but after the first month the rate is 90 min.

BLOOD PICTURE OF PREMATURELY BORN INFANTS

The blood of prematurely born children offers an interesting study. In the first 2 weeks, the average percentage of hemoglobin is 105; in the third week, 93; in the fourth week, 68; in the second month, 55; in the third month, 47; in the fourth month, 50; in the fifth month, 52. The number of red cells begins to decrease after the second month, reaching its minimum in the third month and attaining a normal figure in the sixth month. There is leukopenia in all these babies up to the sixth month. Lichtenstein regards the anemia of prematurely born babies as physiologic.

Frankenstein and Stecher, in a study of the blood picture of prematurely born babies for the first 12 wk. of life, show a lymphocyte average of 72% in the second week and 82% in the fourth week, which drops later to 72%. Segmented forms in the first 5 days are between 20-28%, rising to 35% and dropping to 26% on the eighth day and to 10% in the fourth week. The stabs decrease in the first week from 12 to 4%. Juvenile forms in this period show 0.5-1%.

BLOOD PICTURE OF CHILDREN FROM 1 TO 6 YR. OF AGE

These subjects show a gradual approach of the nursling's blood picture to that of the adult. Note Table 291 of Carstanjen in which are shown changes from the first to the fifteenth year. The decrease in lymphocytes begins definitely about the end of the second year.

CHANGES IN LEUKOCYTIC PICTURE UNDER PHYSIOLOGIC AND PATHOLOGIC INFLUENCES IN INFANCY

Virchow first called attention to digestion leukocytosis. He noted an enlargement of the mesenteric lymph glands after a meal, together with an increase in white cells in the circulating blood. Gregor in 1898 failed to confirm this phenomenon in healthy infants. In 11 cases he found from 3 to 5 hr. after a meal some degree of leukocytosis, but in 6 cases he noted leukopenia. In general, digestion leukocytosis is not constant in infancy. On the contrary there is more likely to be leukopenia. Schiff and Stransky claim that in healthy as well as in artificially nourished infants whether the lymph is disturbed or not after a milk meal leukopenia follows.

No reliable data are at hand as to the shift in the hemogram as a result of the digestion of food.

Wernstedt[877] found the leukocyte count in infants lower while asleep than it was when they were awake. There is lymphocytosis described as a result of efforts in crying, but this disappears after 30 min. of rest. It is probable that the lymphocytes in crying infants and in babies with whooping cough come from the spleen and the thoracic duct. This exercise leukocytosis was first described by Grawitz in 1910.

In intoxications of infants not due to infectious diseases the total white cell count may be elevated up to 20,000. There is a slight shift to the left in such cases. In intestinal decomposition there is a slight shift, and in extreme cases of marasmus there is a definite left shift. In general, however, a left shift speaks for an infection. In acute toxicosis there is leukocytosis.

The significance of eosinophilia in infancy has been the subject of much discussion. In general, eosinophilia is found in all cases of exudative diathesis. This is particularly true of eczemas of infants, but it is believed that eosinophilia is not due to the local process but to the underlying cause of eczema. Figures as high as 65% eosinophils have been noted. Eosinophils in all acute dermatoses are decreased, and they are increased in all chronic cases, particularly in eczema. In erythrodermia desquamativa the leukocyte count is elevated to 12,000 with a high-grade anemia and a count of eosinophils between 1-6%.

LEUKEMIAS IN CHILDREN

Acute leukemia

According to Fraenkel this is a form of leukemia which begins suddenly and has a rapid termination. The first case reported was by Friedreich[878] in 1857. Up to 1889 Epstein had reported 16 cases. Of the 45 cases collected by Theodor[879] in 1897, 9 occurred in children. A monograph of Benjamin and Sluka[880] in 1907 reported 36 cases of acute leukemia in children from the age of 2-14 yr.

These cases in children begin with fever, headache, pains in the legs, weakness, vomiting, and chills. They show a triad of symptoms, anemia, hemorrhagic diathesis, and ulcerative, gangrenous changes in the digestive tract, especially in the mouth. Other workers have described nodular changes in the skin as part of the acute leukemic process. Hemorrhagic diathesis, seen in the form of hemorrhages under the skin and visible mucosae and sometimes rectal hemorrhages, has been reported. Hemorrhage in the cerebrum may lead to hemiplegia. Subperiosteal hemorrhages occur. Swelling around the tibia has been reported. Changes in the central nervous system are seen in the form of polyneuritis.

The lymph glands are enlarged. The spleen is enlarged. The heart is enlarged; there is a small, accelerated pulse. Sometimes hemorrhagic nephritic symptoms are seen. Septic symptoms are noteworthy.

The blood picture in acute leukemia of children shows changes not only in the white cells but also in the erythrocytes and blood platelets. There is a severe progressive anemia combined with subicterus. The red cell count may go below 1,000,000. The hemoglobin does not keep pace with the drop in the red cell count so that the color index is high. Megalocytes and megaloblasts may be seen so that these cases have sometimes been mistaken for pernicious anemia. The number of white cells is so increased that the relativity of white cells to red cells is about 1:100. Wollstein and Bartlett[881] refer to the aleukemic stage of acute leukemia, in which there is marked change in the differential picture but not a great increase in the total number of white cells. In acute leukemia in children, we see large nongranulated single-nucleated cells. These juvenile lymphocytes in the case of acute lymphocytic leukemia are so definite that we can make a diagnosis upon their appearance. In the acute myelocytic leukemias there are many mononucleated cells, the myelocytes of Ehrlich. There are also mononucleated eosinophilic leukocytes. Many mitoses are seen in the white cells. Resort must be had to the Graham oxidase stain to distinguish myeloid from lymphatic cells.

Monocytic leukemia is similar to the leukemia in adults.

Chronic leukemia

Chronic leukemia of children is very uncommon and is confined to chronic myelocytic (granulocytic) leukemia. The spleen enlarges slowly. The lymphatic glands enlarge later. The blood picture is very characteristic. Hemoglobin content and the number of red cells may be normal in the beginning but later decline. Later there are signs of chronic anemia, polychromasia, anisocytosis, and poikilocytosis and presence of normoblasts and megaloblasts.

At times it is necessary to make a differential diagnosis between the blood picture of infectious leukocytosis and that of chronic leukemia in children. In both conditions the count of the leukocytes is increased, but eosinophils and monocytes are low or absent in septic leukocytosis but are present in large numbers in chronic myelocytic leukemia.

Leukemia of nurslings

Congenital leukemia has been described. Its association with chromosomal aberrations has been mentioned previously.

ANEMIAS OF INFANCY AND CHILDHOOD

Anemia is very common in these young subjects. Attention has been called to the discrepancies in the figures of hemoglobin and red cells between infancy and adult ages. The physiologic anemia of premature babies has been considered.

There are a number of hereditary anemias, all hemolytic (discussed in the appropriate sections). These include hereditary spherocytosis, nonspherocytic hemolytic anemia, elliptocytosis, thalassemia, and sickle cell anemia. Erythroblastosis fetalis is also genetically determined.

There are a number of anemias in children and infants which are closely linked to the development of the fetus, the infant, and the young child. Although they fall within the over-all classification of the anemias discussed in previous sections, it is interesting to collect them in one classification as the anemias of infancy and childhood.

- Erythroblastosis fetalis
- Anemias due to
  - Fetal bleeding into maternal circulation
  - Delivery hazards such as abruptio placentae and cesarean section
  - Early tying of the umbilical cord
  - Iron deficiency of the mother
  - Congenital and hereditary factors
  - Iron deficiency aggravating the physiologic iron deficiency
  - Prematurity

In children and infants certain anemias[882] are therefore more common than they are in adults. In early infancy one should consider erythroblastosis fetalis, iron-deficiency anemia, anemia due to blood loss, megaloblastic anemia of infancy, and congenital anemia. In later infancy and childhood the following are added: anemia of infection, aplastic and hypoplastic anemias, and the congenital hemolytic anemias.

Infectious and postinfectious anemia

These anemias follow such infections as congenital syphilis, sepsis, and malaria. In tropical countries, it is often difficult to distinguish between chronic malaria in children and leishmaniasis infantum. In chronic malaria there is an early appearance of fever, gastrointestinal disturbance, spleen and liver edema, and anemia with pallor. In leishmaniasis there is a late development of these symptoms, followed by late fever and gastrointestinal symptoms. In chronic malaria, there is swelling of the liver and spleen, with a sensitiveness of these organs particularly to pressure in the neighborhood of the phrenic nerve. In leishmaniasis there is swelling of the liver and spleen but no sensitiveness. In chronic malaria there are gastrointestinal disturbances more often with constipation than with diarrhea, whereas in leishmaniasis, gastrointestinal symptoms occur but more often with diarrhea than with constipation. The edema in chronic malaria has certain definite localizations, such as the face or the lower extremities, whereas in leishmaniasis the edema is seldom in the face and more often in the lower extremities. In leishmaniasis the blood shows oligemia; erythroblasts are rare. White cells are decreased. There is usually relative lymphocytosis. Resistance of the red cells to hemolysis in hypotonic salt solution is lowered. Parasites may be found in the blood very rarely but can be found in splenic puncture.

Hematoxic anemia

Anemias due to poisons such as lead, potassium chlorate, pyrogallol, etc., are no different in children than they are in adults. There are many cases of lead anemia in infants and children. It is interesting to note that a symptom of lead poisoning in infants is convulsion.

Lead anemia has already been described (see discussion of hematology of lead poisoning). A very important symptom of lead poisoning in children is the deposit of lead in the ends of the growing bones, which can easily be determined by roentgenologic examinations.

Anemia due to intestinal parasites

Severe anemias in children due to intestinal parasites are common. These are seen in connection with infestation with *Diphyllobothrium latum* and *Taenia.* Theodor, Cima, Naegeli, and others have repeatedly called attention to anemias caused by infestation due to *Trichuris trichiura.* Cima, Cozzolino, Ashford, and others have described anemias due to *Ancylostoma duodenale;* and those due to *Schistosoma haematobium* have been described by Kautzky-Bey. Stäubli, van Cott, and others have described the anemias due to trichinosis. Kautzky-Bey claims that *Schistosoma haematobium* and not *Ancylostoma duodenale* is the causative agent of the so-called **Egyptian anemia** in children. Egyptian anemia is characterized by a disturbed relationship between the hemoglobin content and the number of red cells and by the presence of oligochromemia and marked eosinophilia. In trichinosis in children there is at first polycythemia and later slight hypochromic anemia. *Ascaris* and *Enterobius (Oxyuris)* infestations do not often produce anemizing symptoms.

Constitutional anemia

By constitutional anemias is meant those due to some cause other than poisoning or infections. Many of these anemias are due to disturbances of the glands of internal secretion. Some are due to a letdown in the physiologic activity of the hematopoietic organs. In this latter type are seen anemias in connection with the stigmas of congenital defects.

The anemia connected with internal glandular secretory function is seen particularly in myxedema. Here is seen oligocythemia, oligochromemia, relative lymphocytosis, leukopenia, and often eosinophilia. The blood picture is also characteristic in myxedema, namely, lymphocytosis and neutropenia.

Pernicious anemia

True pernicious anemia is seldom if ever seen in children. Most cases are really pernicious anemia blood pictures due to infestations by worms. It is generally conceded that children are not disposed toward pernicious anemia.

Aplastic anemia

Aplastic anemia was first described by Ehrlich in 1888. It has also been called panmyelophthisis of Frank and aregenerative anemia of Pappenheim. For fuller details, see the discussion of aplastic anemia in adults. Eppinger has divided this anemia into 2 classifications—acute and chronic. Typical cases of aplastic anemia are very rare in children. Most so-called aplastic anemia in children is really aleukemic leukemia with aplastic blood pictures.

HEMORRHAGIC DISEASES OF CHILDREN

Basically the mechanisms involved in hemorrhagic diseases in children are similar to those in hemorrhagic diseases in adults. Blood must be obtained by skin puncture, and the test must be modified to allow use of small blood volumes.[883]

Chapter 70

Normal blood findings in domesticated animals

JOHN D. BAUER

The use of various animals for laboratory purposes requires some knowledge of the normal blood picture of these laboratory and domesticated animals.

Guinea pigs: Guinea pigs have an average number of red cells of 5,250,000. The hemoglobin varies from 85-100%, with an average of 94%. The total number of leukocytes varies from 5000-22,000, with an average of 11,000-12,000. Guinea pigs have an average of 350,000 blood platelets/c.mm.

Rabbits: In rabbits the number of red cells varies from 5,000,000-8,000,000,with an average of 6,000,000. Average hemoglobin value is 96%. The number of leukocytes ranges from 8000-13,000, with an average of 11,000. The differential picture is lymphocytes, 45-55%; monocytes, 2-8%; polymorphonuclear cells, 40-50%; eosinophils, 0.5-1%; basophils, 4-8%. An average reticulocyte count of 4-6% is noted.

Cats: Total number of red cells is about 6,000,000. Goodall[884] found the normal to vary from 7,280,000-8,600,000 with an average of 8,000,000. There are 7000-19,000 leukocytes, with an average of 13,300. Goodall found higher numbers of leukocytes. The differential picture is monocytes, 37%; neutrophils, 54%; eosinophils, 9%; mast cells (basophils), 1%.

Dogs: Red cells range from 5,000,000-8,000,000, with an average of about 6,000,000. Hemoglobin values vary from 55-104%, with an average of 90%. Different investigators have reported different quantities of leukocytes in dogs. Six thousand to 12,000 with an average of about 8000 seems to be the normal for adult dogs. The differential picture is lymphocytes, 11-29%, average, 20%; monocytes, 3-10%, average, 6%; neutrophils, 60-76%, average, 68%; eosinophils, 1-10.5%, average, 6%; with basophils very rarely found.

Goats: Red cells are 9,000,000-10,000,000/c.mm. Leukocytes are around 10,000/c.mm.

Sheep: Average number of red cells is 8,000,000 and of leukocytes is 8000. Amount of hemoglobin varies from 47-63%. The percentage of white cells in the differential picture in sheep is lymphocytes, 40-60; monocytes, 3-11; neutrophils, 30-55; eosinophils, 0.2-0.8; basophils, 0-2.

Cows: Red cells vary from 5,000,000-8,000,000, with an average hemoglobin range of 45-85%. Normal number of leukocytes is 5000-10,000. Differential picture, according to Dimock and Thompson,[885] is lymphocytes, 54.2%; monocytes, 1.4%; neutrophils, 30.5%; eosinophils, 13.15%; basophils, 0.59%.

Horses: Normal number of red cells for stallions is from 7,000,000-10,000,000, with an average of 8,000,000; for geldings 5,500,000-9,000,000, with an average of 7,500,000-8,000,000; for mares, 5,500,000-7,500,000, with an average of 6,500,000-7,000,000. The hemoglobin varies from 85-100%. Leukocytes vary from 5000-10,000, with an average of 8000. The differential picture is lymphocytes, 34-38%; neutrophils, 60-65%; eosinophils, 1-2%.

Swine: Normal count of red cells is about 8,000,000, slightly less for young pigs. Hemoglobin values are around 85%. Leukocyte counts are 19,000 with more than 50% of them lymphocytes. The differential picture of swine shows lymphocytes, 56.4%; neutrophils, 38%; eosinophils 5.13%.

White rats: Total blood vol. about 50 ml. The erythrocytes normally show anisocytosis and polychromasia. The polymorphonuclear cells are hypersegmented. The red blood cell count is 8,500,000.

White mice: Hematocrit is 43 vol.%. Normally anisocytosis and polychromasia are present. The red blood cell count is 9,000,000.

Frogs: Large oval nucleated red blood cells are characteristic. The hemoglobin is 60%, and the red blood cell count is 380,000.

Chapter 71

Summary of quantitative changes in blood cellular elements and hemoglobin

JOHN D. BAUER

RED BLOOD CELL CHANGES

Some conditions with high red blood cell counts

Physiologic:

Epinephrine excretion in certain emotional conditions
Compensatory at times in anemia (chlorosis) and in leukemia under x-ray treatment
Certain drugs
Going from a low to a high elevation
Exercise with excessive perspiration
Hormone secretion
Newborn infant
Lowered oxygen tension
Stress polycythemia

Pathologic:

Acidosis
Anoxemia
Apoplexy
Atherosclerosis
Asthma
Bronchitis
Carbon monoxide poisoning
Carcinoma of the esophagus
Cholera
Chronic heart disease with cyanosis
Congenital heart disease
Diarrhea
Emphysema
Hemoconcentration leading to shock
Nephritis, rare
Perspiration, abnormal
Pneumothorax
Poisons, some bacterial and chemical
Polycythemia vera
Pulmonary disease, chronic fibrotic
Splenic tuberculosis
Splenomegaly
Suffocation
Trichinosis at times
Ulcer of pylorus with vomiting
Vomiting
X-ray exposure in moderate doses at times

Some conditions with low red blood cell counts

Physiologic:

Temporarily following injections of fluids

Pathologic:

All anemias and conditions accompanied by anemia, in varying degrees

HEMOGLOBIN CHANGES

Physiologic increase:

Changing from a low to a high altitude
At birth—after the fourth day it drops to 58-75% for the first year and then rises until it is normal at the fifteenth year

Physiologic decrease:

Temporarily after intravenous injections of large amounts of fluid
Premature children as low as 52% during the fifth month of life

Pathologic conditions with normal hemoglobin:

Often in agranulocytosis
Measles
German measles
Parotitis epidemica
Pseudoanemia Sahli
Varicella

Pathologic conditions with increased hemoglobin:

Chronic carbon monoxide poisoning and other conditions with hemoconcentration
Cardiac disease
Dehydrated states
Emphysema
Advanced empyema
Hemoconcentration leading to shock

Pathologic conditions with decreased hemoglobin:

Aleukemia
Amebiasis
Amyloid nephrosis
All anemias
Aplastic anemia
Arthritis
Banti's syndrome
Benzol poisoning

Chagas' disease
Chloroleukemia
Chlorosis
Clonorchis sinensis infestation
Coccidioidal granuloma
Diphyllobothrium latum infestation
Ectopic pregnancy
Egyptian anemia
Enterobiasis (oxyuriasis), untreated
Erythroblastic anemia
Fasciola hepatica—massive infestation
Gaucher's disease
Goat's milk anemia
Hansen's disease
Hematoxic anemias
Hemolytic anemias
Acute hemorrhage
Hodgkin's disease
Hookworm disease
Idiopathic hypochromic anemia
Progressive hypocythemia
von Jaksch's disease
Lead poisoning
Leishmaniasis (kala-azar)
Leukemia
Acute leukemia of children
Chronic leukemia of children
Malaria
Niemann-Pick disease
Ovarian abscess
Paratyphoid
Pernicious anemia
Acute febrile pleochromic anemia of Moschcowitz
Pneumonia, at times slight increase
Poisoning with acetanilid, acetophenetidin, other aniline derivatives, purine, and potassium chlorate
Pseudochlorosis infantum
Pyelitis, chronic
Raillietinosis
Scarlet fever
Schistosoma haematobium infestation
Scurvy
Sickle cell anemia and other constitutional anemias
Sprue
Syphilis and anemia
Syphilis, congenital
Taenia saginata infestation
Trichinosis
Tumors, malignant
Trypanosomiasis
Typhus
Ulcerative colitis

WHITE BLOOD CELL CHANGES

Some conditions with high white cell counts

Physiologic:
Afternoon counts are higher than morning counts
Birth
Digestion
Exercise, including crying of infants
Menstruation
Pregnancy
Pathologic:
Most acute bacterial infections, including those with abscess formation, almost anywhere in the body, one exception being the normal leukocyte count that usually attends brain abscesses
Trauma of all kinds including shock, hemorrhage, surgery, bone fractures, and severe burns
Exposure to drugs and chemicals: Adrenalin, mercury bichloride, venoms of animals such as insect bites, black widow spider bites, and snake bites
Metabolic diseases such as diabetic coma, the nephritides, and scurvy
Death of tissue such as occurs in infarction of organs including coronary occlusion or thrombosis, and embolism of any organ of the body, including the extremities
Mesenteric thrombosis is characteristically associated with a marked hyperleukocytosis
Bleeding into organs or body spaces, such as hemorrhage into ovarian cysts, hemorrhage into the kidneys, or hemorrhage into the pleural or peritoneal cavity
Malignant tumors with marked degenerative changes
Any condition in which intravascular hemolysis occurs, such as severe transfusion reactions due to incompatibility of blood, crises in sickle cell anemia, and fatal blackwater fever
Protozoal diseases during attacks, such as malaria during the chill and congenital syphilis
Parasitic infestation
Some blood dyscrasias, such as polycythemia vera and leukemias

Some conditions with low white cell counts

Physiologic:
Injections of fluids
Neurasthenia
Pathologic:
Anaphylactic shock
Avitaminosis at times
Banti's syndrome
Basedow's disease
Beriberi
Drugs, such as benzol, arsenic, lead at times, mercury, sulfonamides, aminopyrine, urethane, nitrogen mustards, 6-mercaptopurine, gold salts, chloramphenicol, and thiouracils
Empyema when many leukocytes have poured into the area
Felty's syndrome
Food allergies
Gaucher's disease
Granulomas at times, sarcoid
Infections, bacterial, such as typhoid fever and some cases of brucellosis (paratyphoid usually accompanied by a normal or slightly elevated white blood count)
Infections, viral, such as influenza, dengue, infectious mononucleosis (questionable virus), measles, pappataci fever, epidemic parotitis, poliomyelitis, vaccination, smallpox, scrub typhus or tsutsugamushi fever, and infectious hepatitis
Infestation, protozoal, such as disseminated histoplasmosis, kala-azar, malaria, trypanosomiasis, and yellow fever

Overwhelming infection, especially of the debilitated or of elderly people; may be due to bacterial organisms of an acute type or may be associated with widespread disease such as miliary disseminated tuberculosis
Hematologic disorders, such as agranulocytosis, aleukemic leukemia, aplastic anemia, infectious mononucleosis, and pernicious anemia
Irradiation, either in the form of products of fission, such as the atomic bomb or radioactive isotopes, or exposure to x-ray
Myxedema
Osteoscleroses, diffuse
Paroxysmal hemoglobinuria during attacks
Pellagra
Splenomegalic diseases other than those listed here manifesting hypersplenism
Primary splenic neutropenia
Sprue
Vaccination, occasionally
Yellow fever at times

SUMMARY OF CHANGES IN BLOOD PLATELETS

Physiologic increase:
At birth (not constant)
Marathon runners
After administration of certain medicaments, e.g., diphtheria antitoxin, epinephrine, pyrodin, and hypotonic saline and sodium nucleinate by mouth
After operations (not constant)
Blood which is shut off from circulation in a doubly ligated vein
Pathologic increase:
Bubonic plague
Often in chronic hemolytic icterus
Febrile period of acute infections
Hemolytic anemias
Chronic myeloid disease
Pneumonia
Polycythemia vera
Posthemorrhagic anemia
Sickle cell anemia
Typhus
Physiologic decrease:
After eating
After administration of certain drugs, e.g., arsphenamine, calcium, atropine, saponin, antimony, corpus luteum extract, tuberculin, and phenylhydrazine
Menstruation
Pregnancy
Senility
Pathologic decrease:
Aleukemic leukemia
Idiopathic aplastic anemia
Benzol poisoning
Acute infections during incubation periods
Jaundice
Kala-azar
Acute leukemia
Diseases of the liver
Lymphocytic leukemia
Panmyelophthisis
Pernicious anemia
Purpura, thrombocytopenic
Scarlet fever
Trauma
Uremia
Varicella at beginning of fever

Section Two

BLOOD GROUPS, TRANSFUSION, AND MEDICOLEGAL APPLICATIONS*

The subject of blood grouping and transfusion, with medicolegal applications, has assumed such gigantic proportions within recent years that to cover all phases of the subject thoroughly would require not one chapter but perhaps a library of information. It is the purpose of this section to discuss the subject primarily for use in the routine examinations of patients and donors prior to and at times following transfusions; in the examination of patients and at times donors for unusual blood factors or types; to explain the use of the blood group factors and types in genetic studies for clinical and medicolegal applications; in the identification of blood stains, semen, saliva, and other body fluids; and in transfusions and other applications. In addition to detailing methods for routine examination of blood, specialized technics will be described for the so-called "rare" blood factors, the protection of the recipient of a transfusion, the protection of the donor, the liability laws involved in blood transfusions, the implication of the blood factors and their importance in pregnancy, and other allied subjects.

Thorough and strict adherence to technic is a prerequisite for all laboratory investigation, but in the field of blood grouping serology improper or sloppy methods or failure to use enough controls and to use them properly can result in loss of life. The salient facts regarding technics of handling material for blood grouping experiments will be given in detail. Outdated or weak-reacting reagents contribute to mistakes in the serologic laboratory. This subject and the "blind"[1] test as a means of preventing or correcting errors will be included. The latest advances in methods will be given, any obsolete method will be deleted, and there will be a comprehensive review of all blood factors known to date, together with synonyms when such exist. An attempt will be made to simplify a complicated subject, but oversimplification will be avoided inasmuch as a false sense of security in a knowledge not possessed might lead to death of a patient.

In accordance with the recommendations of the Committee on Nomenclature of the American Medical Association, blood agglutinogens will be designated by ordinary type, genes by *italics,* and blood factors by **bold-faced type.** In the main, the nomenclature suggested by A. S. Wiener will be followed. The English nomenclature will be discussed but will not be used in the text except for discussion and comparison with the International Nomenclature.

Since the first edition of this textbook, which was published in 1935, blood grouping has developed into a science of vast proportions. Many of the old concepts have had to be modified, and as new blood factors have been discovered even those findings assumed to have been correct but a few short years ago have had to be modified in the light of modern investigation. Although much of the knowledge concerning blood groups and blood factors is primarily useful in the field of legal medicine and genetics, much applies to clinical practice. The serologist and technologist working in blood banks or in clinical laboratories today are required to have a working acquaintance with all the developments in this complex subject. Many of the older methods have given way to new and improved technics, and these must be applied skillfully so as to avoid errors.

---

*We are indebted to Dr. Lester J. Unger, Director of the Blood and Plasma Bank, New York University Medical Center, New York, N. Y., for his kind assistance in the revision of this section, and to Dr. Alexander S. Wiener, Senior Bacteriologist (Serology) to the Office of the Chief Medical Examiner of New York City, Adjunct Associate Professor in the Department of Forensic Medicine of the New York University Postgraduate Medical School, and Attending Immunohematologist to the Jewish and Adelphi Hospitals of Brooklyn, N. Y., for his assistance, criticisms, and advice in the preparation of this section. Besides giving the benefit of their advice and suggestions, both Dr. Unger and Dr. Wiener permitted Mrs. Erskine to work in their laboratories to obtain first-hand knowledge of their technics so that these could be incorporated in the section.

There are at the present more than 50 known factors that determine individual serologic differences among human beings. Of these, 3 are of paramount importance, **A**, **B**, and **Rh**$_0$, since these are the most frequent sources of clinical problems. Although opportunity for isosensitization, by pregnancy and transfusion, to the other blood factors, such as **M**, **N**, **S**, **U**, **P**, **rh′**, **rh″**, **hr′**, **hr″**, **K**, **Duffy**, etc., constantly occur, examples of isosensitization are relatively uncommon, indicating that these are less antigenic than blood factors **A**, **B**, and **Rh**$_0$. Certain individuals have a special propensity to form antibodies, as shown by reports of instances of multiple sensitization to a number of different blood factors more often than can be ascribed to chance alone. In some instances the sensitized individuals have autoantibodies as well as group-specific antibody; for example, Wiener et al.[2] have not infrequently found autoantibodies in the serum of individuals sensitized to both factors **hr′** and **hr″**.

Individuals who are negative for the **Vel**, **Tj**^{a}, **Rh**^{A}, **Rh**^{B}, **Rh**^{C}, **Rh**^{D}, **hr**^{S}, **U**, and **I** factors are quite rare, so that opportunities for sensitization are few and seldom occur. If incompatibilities are detected in cross-matching tests preliminary to a transfusion, the problem of finding a compatible donor will be simplified if the blood factor or factors responsible for the incompatibility can be identified. One way of finding such a donor is to test the patient's serum against a panel of selected group O cells known to contain a varied assortment of the numerous blood factors that have been identified to date, as suggested by Unger in 1954.[3] By the use of such a panel, Wiener et al. quickly identified an antibody in the serum of a mother of an erythroblastotic baby as anti-**S**. The limitation of such panels is that they are unlikely to include bloods of the very rare types and are therefore of no value for identifying antibodies such as anti-**U**, anti-**I**, anti-**Vel**, anti-**Kj**^{a}, etc.

The most important clue to identifying antibodies is that antibodies for blood factors of different blood group systems behave differently. Rh-Hr antibodies can generally be recognized by the sharp reaction given by most of the known technics: conglutination, antiglobulin, and especially the proteolytic enzyme method. Cells that are maximally coated with any antibody of the Rh-Hr system generally give equal titers with the same antiglobulin serum. **Duffy** and **Kidd** antibodies, however, generally act best by the antiglobulin method, and cells maximally coated with such antibodies generally react with antiglobulin sera to $\frac{1}{10}$ the titer of cells maximally coated with Rh antibodies. **Kidd** antibodies react best in serum from freshly drawn blood. **K-k** antibodies have properties intermediate between those of the **Rh-Hr** and the **Duffy** antibodies. Antibodies of the M-N system not infrequently react on saline-suspended unmodified cells, but when the cells are treated with proteolytic enzyme, the type-specific reaction disappears and is replaced by a nonspecific one. **Vel** antibodies can be recognized by their capacity to produce hemolysis in vitro as well as from the very low incidence of compatible red blood cells.

Caution

With the increase in the number of transfusions and the discovery of so many blood factors not heretofore known, it has become increasingly evident that blood grouping is a highly specialized field, and these delicate tests must be carried out with precision by specially trained personnel if fatal hemolytic reactions are to be avoided.

Chapter 72

General considerations

ADDINE G. ERSKINE

HISTORY OF BLOOD TRANSFUSIONS

The first record of a blood transfusion is referred to in classical literature: Medea attempted to rejuvenate old Anchises by removing blood from his cervical vessels and replacing it with juvenile blood (Ovid). Obviously no genuine blood transfusion could have been performed prior to the discovery of the circulation of blood. Clark and Henshaw, soon after the discovery of the circulation of blood by William Harvey in 1616, began to make animal experiments on blood transfusion. Denys and Emmerez of Paris in 1667 made a direct transfusion of the blood from the carotid artery of a sheep into the cubital vein of a human patient, and good results followed. Others repeated this, but disastrous results occurred in some cases, so that it was abandoned.

Blood transfusion was revived during the past century. However, because severe reactions and death followed the transfusion of incompatible bloods, the procedure was practically abandoned for many years. It was revived only when methods were discovered for determining the compatibility of human bloods. At the present time methods of blood grouping and blood matching have eliminated many of the dangers incident to transfusion. It is now known that in most instances the unfavorable reactions are due either to hemolysis or to agglutination of either the donor's or the recipient's blood cells or to both.

HISTORY OF DISCOVERY OF THE FOUR PRINCIPAL BLOOD GROUPS—O, A, B, AND AB

In 1901 Landsteiner[4] established the basis for the present methods of determining compatibility or incompatibility of bloods for transfusions. He discovered that all human beings can be divided into 3 distinct groups. He showed that the identity of each group depended upon the presence on the red blood cells of "isoagglutinogens." The 3 blood groups he called A, B, and C (not O). Group C was later called O. A fourth group was discovered by von Decastello and Sturli,[5] the latter a pupil of Landsteiner's. This was the AB group. It was found that in the case of group A, the serum reacted upon the corpuscles of group B, causing them to clump or agglutinate, but the serum of group A did not react upon the corpuscles of group A. The corpuscles of group A, in turn, were agglutinated or reacted upon by the serum of group B, but the serum of group B did not react upon the corpuscles of group B. It is obvious, therefore, that normally the corpuscles are apparently not sensitive to their own sera or generally not to sera of other individuals belonging to the same blood group (see subgroups, p. 1470).

Four principal blood groups are now recognized, designated as groups A, B, AB, and O. These belong to a blood group system designated the A-B-O system. This is the International Classification of the blood groups. The 2 other classifications of the same blood groups, the Moss[6] and Jansky,[7] are no longer used, but merely as a matter of historical record their equivalents according to the International Classification are given in Table 296.

Approximately 45% of American and European peoples belong to group O, 42% to group A, 10% to group B, and 3% to group AB. The International Nomenclature, officially recognized by the Health Committee of the League of Nations, is the same as the original classification of Landsteiner and von Dungern and Hirszfeld, and it is the nomenclature of choice. To avoid confusion, the group names of Moss and Jansky have been eliminated from medical literature.

A further interesting communication upon blood groups was that by von Dungern and Hirszfeld,[8] who discovered the existence of subdivisions or subgroups in 2 of the 4 human blood groups. These subdivisions have now been extended to include many more.

The substances that characterize the A-B-O blood groups are present in practically every tissue of the body and have been found in soluble form in the serum, saliva, gastric juice, semen, urine, etc. of the so-called "secretors."

DISCOVERY OF OTHER BLOOD TYPES AND BLOOD FACTORS AND CLASSIFICATION INTO SYSTEMS

In 1927 Landsteiner and Levine[9, 10] noted that when certain immune sera from rabbits previously injected with human blood were absorbed with certain samples of human blood, they still contained agglutinins acting on the majority of bloods of all 4 groups but not upon all. This led to the discovery of the blood factors **M** and **N**, which determine the agglutinogens M and N. Either M or N agglutinogens or both were found to be present on all human blood cells, but natural anti-**M** or anti-**N** agglutinins are only rarely found in human sera. Such antibodies are produced by injecting rabbits with the appropriate type of cells. Research since the initial discovery has demonstrated that all human bloods may be divided into 3 types, M, N, and MN. Agglutinogens M and N are transmitted by heredity just as are the agglutinogens of the A-B-O system.

The **M** and **N** factors are of almost no importance with respect to blood transfusion work because there are hardly ever any anti-**M** or anti-**N** agglutinins in normal human blood sera, and M and N agglutinogens are apparently only feebly antigenic for human beings. (For exceptions refer to p. 1552.) They are important in questions of paternity, in family studies, and in other medicolegal work but are unreliable in the identification of dried blood stains. This is described on pp. 1599-1618ff.

The discovery of the Rh factor by Landsteiner and Wiener in 1937 and the report of its finding in 1940[11] constitute the most important advance in the field of blood grouping serology since the discovery of the 4 principal blood groups. With its discovery blood grouping serology was given a new impetus. New terms are now used to describe attributes of the red cell antigens, the nature of antibodies has been studied and further clarified, and the study of the genetics of the blood types has been amplified.

Blood group systems: The various blood groups now are recognized as belonging to certain systems, of which there are 9 principal ones, and some unclassified. These 9 are A-B-O (and Lewis), M-N-S-U, P, Rh-Hr, K-k (Kell), F-f (Duffy), J-j (Kidd), Lu (Lutheran), and Di (Diego). The most complex of all the systems is the Rh-Hr.

Other important discoveries: Inheritance of the 4 Landsteiner blood groups was demonstrated by Ottenberg and Epstein in 1908[12] and von Dungern and Hirszfeld in 1910.[13] The exact mechanism of heredity of the blood groups was solved by Bernstein in 1925.[14] The inheritance of the Rh-Hr types was worked out by A. S. Wiener and his collaborators. Other important discoveries have been reported, and these will be listed when the individual systems are discussed.

GENERAL TERMINOLOGY USED IN BLOOD GROUPING SEROLOGY*

Antigen: The term "antigen" refers to any substance which, if injected into human beings or other animals, stimulates the production of antibodies, immune bodies capable of reacting with or destroying the antigen. In the case of blood grouping, the antigen is found on the red cells and is also recoverable in solution in certain body fluids and secretions in individuals known as secretors.

Antibody: An antibody is an immune substance formed in response to the stimulus of an antigen. It reacts with the antigen that called it into being. It is found in the plasma and is recoverable in the serum or plasma. Cross reactions also occur; for example, anti-**A** can react with sheep cells as well as with human A and AB cells.[15]

Agglutinogen: An agglutinogen is a substance present on the surface of red blood cells which, when combined with the corresponding specific antibody, results in clumping or agglutination of the red cells. An agglutinogen may have many factors, each factor capable of stimulating production of or combining with a specific antibody.

Blood factor: Agglutinogens of red cells are generally characterized by a number of "blood factors," which are serologic specificities by which agglutinogens are recognized. An agglutinogen may have multiple factors, all transmitted as a block by heredity. The blood factors are not necessarily limited to the cells of human beings. For example, if a blood contains factor **A**, the cells are clumped by a serum that contains **anti-A** agglutinin, but this does not necessarily mean that those blood cells have agglutinogen A of the **human** group A blood. There are many agglutinogens other than that of the human blood group A that react with particular anti-**A** sera, specifically an agglutinogen of sheep cells. As another example, some of the blood factors **B** which characterize agglutinogen B of human blood are shared by agglutinogens of the red cells of rabbits and other rodents.[16]

---

*For a more complete glossary, refer to pp. 1487ff.

As another example of blood factors present in a single agglutinogen, blood of type Rh$_1$ may contain, in addition to factors **Rh**$_0$ and **rh′**, many other factors such as **rh**$_i$, **Rh**^{A}, **Rh**^{B}, **Rh**^{C}, **Rh**^{D}, **rh**^{G}, **hr″**, **hr**^{S}, and **Hr**, but it lacks **rh″**, **hr′**, **hr**, **rh**^{w}, **rh**^{x}, **rh**$^{w}_{2}$, and **hr**^{V}. Wiener predicted that the number of blood factors characterizing any Rh-Hr agglutinogen is theoretically unlimited and depends largely on one's enterprise and ingenuity in finding antisera of new specificities, but he made no attempt to anticipate the nature of the specificity of blood factors still to be found since this is generally unpredictable. New blood factors usually are identified after an antibody has been found in a serum following transfusion or in pregnancy.

The prefix "iso-": The prefix "iso-" in blood grouping serology usually refers to human agglutinogens and agglutinins in the A-B-O system, except when it is used to describe a reaction of isoimmunization. In the latter case it means formation of antibodies by a member of a species of an animal or by a human being in response to an antigen present on the cells of a member of the same species. For example, a human being of type rh (Rh negative) may form anti-Rh isoantibodies as a result of a transfusion of human blood containing the Rh agglutinogen; the transfused person has been isoimmunized against the Rh agglutinogen. Such isoimmunization occurs in pregnancies as well as in transfusions (pp. 1508-1509).

Agglutinin: The term "agglutinin" refers to an antibody in the blood serum which has the ability of reacting with its specific agglutinogen to cause the cells containing that agglutinogen to clump or "agglutinate." Refer to p. 1512 for the nature of antibodies.

Agglutination: Agglutination means the clumping of cells. In blood group nomenclature, agglutination refers to the clumping of red cells by action of a specific serum. False appearance of agglutination due to causes other than antigen-antibody reactions is referred to as **pseudoagglutination.** An example of pseudoagglutination is rouleaux formation, such as is found especially in individuals with very high sedimentation rates.

Blood group system: The division of various blood types into systems depends on their hereditary transmission, and knowledge of such transmission must often depend on family studies along with serologic investigations. Certain terms must be used in these studies.

Genotype: Genotype refers to the constitutional make-up of an individual as determined by heredity. Genotypes are transmitted through the germ cells by means of their chromosomes. The make-up of an individual in terms of his genes is known as his genotype.

Gene: Genes are units of inheritance. These genes are arranged in a linear fashion along the chromosomes.

Phenotype: Phenotype refers to the characteristics of individuals of a species as determined by direct observation, measurement, or chemical or serologic testing.

AT WHAT AGE DO AGGLUTINOGENS AND AGGLUTININS APPEAR IN THE BLOOD?

Kemp[17] showed that the isoagglutinogen could first be demonstrated in the red blood cells of a fetus of 37 days and demonstrated that the sensitivity of the cells increases throughout antenatal and postnatal life up to the age of 20 yr., after which time it remains constant.[18] He also noted that the red blood cells of the newborn infant generally have only 20% of the sensitivity to agglutination that adult blood cells have. Expressed in other terms, a serum with a titer of 500 against adult corpuscles would usually agglutinate the corpuscles of the newborn infant only up to a titer of 100. Thomsen and Kettel[19] determined the titer of the isoagglutinins in the sera of individuals of various ages and found that isoagglutinins begin to appear in the latter half of antenatal life and rapidly increase in titer after birth up to the age of puberty, when the titer gradually diminishes. The average titer of the anti-**A** agglutinin is generally higher than that of anti-**B.** Wiener states that whereas isoagglutinogens are demonstrable at birth, only about half of all newborn infants have demonstrable isoagglutinins. Hirszfeld[20, 21] believed that any isoagglutinins at birth are derived from the mother by filtration through the placenta. (See factor **C** of the A-B-O system, p. 1472.) Smith[22] studied the isoagglutinogen and isoagglutinin of the blood of infants from day to day during the first few weeks of postnatal life and found that whatever isoagglutinins were present at birth diminished in titer or disappeared during the first 10 days of life, after which time new isoagglutinins appeared.

Bornstein and Israel[23, 24] made a study of agglutinogens in fetal erythrocytes, particularly the M and N agglutinogens. Moureau[25] demonstrated the **M** and **N** factors in very young fetuses. Hyman[26] found **M** and **N** demonstrable in 3 fetuses but failed to obtain either **M** or **N** in the fourth, at 3 mo., the cells of which exhibited the isoagglutinogen B. She left the question open whether they had not yet developed at that time. Bornstein and Israel's study[23] comprised a larger series of fetuses to determine whether or not their agglutinogens are detectable with sera and testing fluids used in transfusion work and in legal tests. By including the Rh factor in the investigation, information could be obtained on the value of tests performed with fetal blood for investigations of isoimmunization as a cause of habitual abortion, according to Levine et al.[27] Bornstein and Israel's series comprised 19 premature fetuses, only those showing gross evidence of maceration being omitted. Blood was taken from the heart, suspended in physiologic saline solution, and examined the same day with the centrifuge method. Examination of parents was possible in some cases. Various human **A** and **B** antisera and **M** and **N** testing fluids were used, which gave positive agglutinations with the corresponding cells in a dilution of 1:8. For the Rh tests the test tubes were incubated for 1 hr. at 37° C. before centrifugation.

The fetuses varied in length from 7 to 50 cm., the average being 28.6 cm. The distribution of agglutinogens was independent of the length of the fetuses and did not grossly deviate from the percentages in the population. No fetus without either **M** or **N** was encountered, and no combination parent type M, fetus N, or vice versa, occurred. The Rh factor was demonstrable in 4 out of 5 fetuses. This confirms the indirect evidence that the Rh factor is present early in fetal life.

Table 292 gives the summary of Bornstein and Israel's work.

Table 292. *Blood groups and blood types of fetuses and parents (presence or absence of Rh factor tested in Nos. 15-19 only)*

Fetus				
No.	*Length (cm.)*	*Agglutinogens*	*Mother*	*Father*
1	21	O MN	O M	
2	7	O MN	B M	
3	13	A M	A M	
4	47	O MN		
5	23	A M		
6	13	O M	O MN	O MN
7	30	A MN	A MN	A MN
8	50	A M		
9	42	A N		
10	27	A MN		
11	19	O N		
12	26	B M		
13	30	A N		
14	33	B N	A MN	
15	41	AB M Rh+	A MN Rh+	
16	42	A M Rh+	O MN Rh+	
17	39	A MN Rh−	A MN Rh−	
18	17	O N Rh+	A N Rh+	
19	21	B MN Rh+	A MN Rh−	B N Rh+

This research demonstrated agglutination of A, B, M, N, and Rh in the heart's blood of 19 fetuses. This seems to prove that agglutinogens are actually developed long before birth and in sufficient strength to make the examinations reliable enough for scientific purposes.

IDENTIFICATION OF BLOOD GROUPS

Blood groups are identified by means of agglutination reactions—the clumping of cells by action of a serum. The antigen or agglutinogens are on the blood cell surfaces, which makes them agglutinable or able to clump when mixed with a serum containing the corresponding antibody or agglutinin. In the A-B-O system the agglutinogens are classified as A or B and the agglutinins as anti-**A** or anti-**B**. (The so-called "O" agglutinogen will be discussed elsewhere, p. 1454). Each agglutinin in the serum acts upon cells containing the corresponding agglutinogens; thus anti-**A** clumps cells that contain agglutinogen A, and anti-**B** clumps cells that contain agglutinogen B. Group O has neither A nor B agglutinogen, group A has A agglutinogen, group B has B agglutinogen, and group AB has both A and B agglutinogens.

Antibodies in the sera are designated as either anti-**A** or anti-**B**. Group O has both anti-**A** and anti-**B**, group A has anti-**B**, group B has anti-**A**, and group AB has neither antibody. Anti-**A** will cause clumping of cells containing agglutinogen A, and anti-**B** will cause clumping of cells containing agglutinogen B. An anti-**A** serum thus will cause clumping of cells of groups A and AB, whereas an anti-**B** serum will cause clumping of cells of groups B and AB. Group O cells will not be agglutinated by either serum.

All blood groups and types are identified by their agglutinogen content; thus type M has agglutinogen M, type N has agglutinogen N, and type MN has both agglutinogens M and N. Type Rh_0 has agglutinogen Rh_0, etc.

The serum that acts upon cells containing agglutinogen M is called anti-**M**, and the serum that acts on cells containing agglutinogen N is called anti-**N**. This nomenclature is used in all the systems. Anti-**M** and anti-**N** agglutinins are not found naturally in human serum except in extremely rare cases. Both anti-**A** and anti-**B** are natural antibodies. Further identification of blood types by their factors is found throughout this section.

COMPOSITION OF A-B-O SYSTEM

Whereas group O cells have neither A nor B agglutinogen, the serum contains both anti-**A** and anti-**B** agglutinins. The cells of group O, therefore, are not agglutinable by any sera of this system, but the serum of group O will cause agglutination of cells of groups A (containing A agglutinogen), group B (containing B agglutinogen), and group AB (containing both A and B agglutinogens).

In group A the cells have agglutinogen A and the serum contains agglutinin anti-**B**. Thus group A cells are agglutinated by group O serum (containing anti-**A**) and by group B serum (containing anti-**A**). The serum of group A, which contains anti-**B** agglutinin, will cause clumping of cells of group B (containing B agglutinogen) and group AB (containing A and B agglutinogens).

In group B the cells have agglutinogen B and the serum contains agglutinin anti-**A**. Group B cells therefore are agglutinated by group O serum (containing anti-**B**) and group A serum (containing anti-**B**). The serum of group B contains anti-**A** agglutinin and therefore causes clumping of cells of group A (containing A agglutinogen) and group AB (containing A agglutinogen as well as B agglutinogen).

Group AB blood has both agglutinogens A and B on the cells and therefore these cells are agglutinated by group O serum (containing anti-**A** and anti-**B**), group A serum (containing anti-**B**), and group B serum (containing anti-**A**). The serum of group AB, however, has neither anti-**A** nor anti-**B** agglutinin and therefore will not cause clumping of cells of any of the four groups.

No reaction occurs when either the agglutinogen or the agglutinin is lacking or when the agglutinin and agglutinogen are not specific for each other, that is, **not** designated by the same letter.

Anti-**A** is sometimes called alpha (α), and anti-**B**, beta (β). Anti-**A** reacts only with cells containing A agglutinogen, and anti-**B** reacts only with cells containing B agglutinogen.

It is now generally known that group O cells are characterized not only by absence of agglutinogens A and B but also by the presence of a special agglutinogen O. Only rarely do natural antibodies for agglutinogen O occur in human sera, and these are found in subgroups A$_1$B and A$_1$, in animal sera, especially from cattle and eels, and they have been produced by heterogenetic immunization of goats with Shiga bacilli. These antisera are of low titer and low avidity and give a marked gene dose effect, so that bloods containing the property in a single dose, for which such tests would be most useful, generally give indistinct reactions.

Table 293. *Composition of A-B-O blood groups*

Blood group	*Agglutinogen on cells*	*Agglutinin in serum*	*Cells are agglutinated by sera of group*	*Serum causes agglutination of cells of group*
O	Neither A nor B	Anti-**A** and Anti-**B**	None	A, B, AB
A	A	Anti-**B**	O, B	B, AB
B	B	Anti-**A**	O, A	A, AB
AB	A and B	None	O, A, B	None

A	II	II	42
B	III	III	10
AB	IV	I	3

Extracts of *Ulex europaeus* seeds give agglutination reactions resembling those of anti-**O** serum, but they are not specific for blood group O, since the *Ulex* seed extract, like anti-**O** sera in general, tends to react most strongly not only with red cells from individuals of group O but also of subgroup A$_2$. The reagent is now designated "anti-**H**" and is most useful in diagnosing the secretor types. The reagent gives sharp reactions despite its low titer and is used for testing saliva of individuals of any A-B-O group.[28, 29] The secretor tests are described on pp. 1542-1544.

SAFE TRANSFUSIONS

In order to ensure safe blood transfusions (pp. 1464ff) that is, in order to prevent what is known as incompatibility reactions, certain preliminary examinations must be made of both the recipient's and the donor's blood. These are as follows (details in Chapter 73):

1. Obtain the blood group of both the recipient and the donor by testing the cells with known anti-**A** and anti-**B** sera, and check these results by testing each of the blood sera

(recipient and all donors), previously inactivated, against known A_1 and B cells.

2. Obtain the subgroup if the recipient is group A or group AB.
3. Cross match the recipient's serum with the donor's cells and the recipient's cells with the donor's serum.
4. Determine the Rh factor in the cells of the recipient and of the donor.
5. During the cross-matching tests, make tests also on both the donor's and the recipient's sera for possible Rh-Hr or other antibodies; such tests are called "sensitivity tests." Refer to p. 1482.

Caution: A serologic test for syphilis should be performed on all prospective blood donors to exclude syphilis. It is well to bear in mind the possibility of transmitting malaria in blood transfusions. It is best not to transfuse blood of an allergic individual. The subject of transference of homologous serum jaundice is discussed on pp. 1568, 1585, and 1591.

SPECIFIC AGGLUTINATION

When the red blood cells of a normal human being are suspended in physiologic saline solution, an even suspension results, although upon standing the cells will settle. If this even suspension of cells is mixed with serum of the same individual or of another individual of the same blood group, the suspension is apparently unaffected. If, however, blood serum of an individual of an incompatible blood group is added to this even cell suspension, the red blood cells come together in clumps, which is the phenomenon of agglutination and is the basis for division of all individuals into the 4 principal groups and the means of identifying the numerous blood types and blood factors. The agglutination of cells when mixed with serum depends upon a specific reaction between 2 substances, 1 on the red cells called "agglutinogen" and 1 in the serum called "agglutinin." Each agglutinin is specific for a certain agglutinogen and each agglutinogen reacts with a specific agglutinin, although in the light of modern investigation it is incorrect to assume a simple 1:1 correspondence between agglutinogen and antibody, as Wiener and others have pointed out from time to time. For example, in the Rh-Hr system, each agglutinogen is characterized by multiple serologic factors which are inherited in a block by means of corresponding Rh-Hr allelic genes.

Agglutination tests may be made either on the open slide or in tubes. In either case cells are mixed with serum. Either the cells or the serum may be unknown, or if both are known, this is called a "control." If the cells are unknown, the agglutinin in the serum must be known in order to identify the cells. If the agglutinin is unknown, then known cells must be used to identify the serum. Suitable controls must always be made with every blood grouping experiment to ensure reliable results.

True agglutination occurs when definite clumps of red blood cells are found. When the concentration of antibodies in the serum is high (high titer serum), the clumps will be large, brick red, and definitely separated from each other, or one large clump may appear, and individual cells will not be identifiable in the clumps upon microscopic examination. When high titer serum is used, macroscopic examination reveals the agglutination in most cases.

There are many degrees of agglutination, designated by Unger as +++S, +++W, ++S, ++W, +S, +W, ±, and negative (−). S = strong; W = weak. The weaker agglutination reactions are visible only under the microscope, and the color of the clumps is not as red as when the clumps are large; often the clumps appear star-shaped and brownish. One must guard against false appearance of clumping, settling of cells, and other nonspecific agglutination reactions. By adding a drop of saline to the slide after sufficient time has been allowed for agglutination to take place, then rapidly rotating the slide and reading microscopically, such false appearance of agglutination and settling of the cells will usually be avoided.

False negative reactions

If testing sera are of high titer, the reactions are so definite with the open slide method that it is practically impossible to mistake them. However, if one uses whole blood as the unknown in testing for A-B-O blood groups or in the controls, the reactions are difficult to read if the mixture of blood and serum is not spread thin on the glass slide or if saline is not added after sufficient time has elapsed for the reaction to take place. When testing unknown sera against known cells, the antibody concentration is not controlled, and weak positive reactions might occur. The same is true in cross matching, in which the drops must be searched diligently for slight clumping. Likewise, antibody titer gradually decreases in ampuled sera, so that controls must always be made before using such testing sera.

If weak-reacting blood grouping sera are used, either the reaction might be overlooked or it may fail to take place. If a weak anti-**A** serum is used, it could fail to detect the weak A agglutinogen of subgroup A_2 or A_2B cells. Thus a subgroup A_2 blood would be erroneously classified as group O, and a subgroup A_2B would be erroneously classified as group B. If the anti-**B** serum is weak, it might fail to detect the B agglutinogen on group B and AB cells, erroneously classifying a group B blood as group O and a group AB blood as group A. In all blood grouping in the A-B-O system, tests must be made using the serum of the unknown against known A and B blood cells, as well as tests on the cells using known antisera. This will help eliminate errors which may be made inadvertently, especially in the subgroups (refer to subgroup B_3, p. 1474).

Another source of error may be low sensitivity of agglutinogens, which is seen when testing blood of newborn infants or at times when using preserved blood suspensions. As already mentioned, one of the most common errors is to mistake subgroup A_2B blood for group B because of the weak reactivity of the A agglutinogen in such blood. The use of high-titered anti-**A** sera will obviate such results. (See p. 1459.)

NONSPECIFIC AGGLUTINATION

False positive reactions

Pseudoagglutination: Pseudoagglutination is the false appearance of agglutination that is not true agglutination at all but usually rouleaux formation of the red blood cells. It simulates true agglutination. It is produced by high concentration of serum and high temperatures and has been noted when tests are made on open slides in an air current. It occurs in the slide test because of the low dilution of the serum and because the large surface favors evaporation and concentration of the serum. Serum from patients with rapid sedimentation rates will produce rouleaux formation with any red blood cells, including their own.

One must be cautious to avoid pseudoagglutination when using gum acacia, gum tragacanth, and gelatin. Care must be exerted in reading reactions when trypsinated or ficinated cells are used. A negative control for comparison, prepared just like the test, must always accompany such tests.

The difference between pseudoagglutination and true agglutination can be readily seen under a microscope. In rouleaux formation the red blood cells are arranged in piles like a stack of coins. By adding a few drops of saline, rouleaux formation or pseudoagglutination will usually disappear, whereas true agglutination either is not affected by this procedure or at times is made even more apparent.

Bacteriogenic agglutination — Huebner-Thomsen or panagglutination phenomenon: Bacteriogenic agglutination is a phenomenon unrelated to isoagglutination and results from bacterial action. It does not occur when fresh blood and serum are used. It is seen in some samples of stored blood in which the cells are clumped by any normal human serum, including that of the individual from whom the blood was derived and also by group AB serum which ordinarily does not clump any cells.

Bacterial contamination also affects blood sera which then cause agglutination of red cells of several groups as well as their own groups. It may be avoided by using only freshly drawn or sterile blood.

Autoagglutination: Autoagglutination is a condition in which the serum agglutinates its own red blood cells, due to the presence of an absorbable agglutinin in the serum and a corresponding agglutinogen on the cells. Autoagglutinins act not only on the subject's own cells but also on the cells of all other human beings, regardless of blood group, and are therefore **panagglutinins.** The reaction occurs most often in tests made at low temperature. It usually disappears upon warming and reappears upon chilling.

In certain pathologic conditions the cold autoagglutination titer is considerably increased so that the reaction may occur also at room temperature. Such conditions are atypical pneumonia, paroxysmal hemoglobinuria, syphilitic or hypertrophic cirrhosis of the liver, hemolytic icterus, Raynaud's syndrome, trypanosomiasis of man and animals, severe anemias, and other conditions. These autoagglutinins at room temperature are a source of error in blood grouping, especially when the titer is high. In some cases of Hodgkin's disease and febrile tuberculosis it is impossible to perform a red blood count, as pointed out by Gradwohl, and also difficult to determine correct blood groups.

The serum can be freed of the interfering autoagglutinins by separating it from the cells at 0°-5° C., at which temperature the blood cells absorb the autoagglutinins. The cells should be washed with warm saline (37° C.) before cross matching.

"Cold" agglutination: Cold agglutination is due to the taking up of adsorbable antibodies in the cooled state. Since cold agglutination occurs in human bloods exposed to temperatures 0°-15° C. and is prevented by higher temperatures, this factor must be borne in mind when conducting tests.

Secondary coagulation simulating agglutination: Tests made with unwashed cell suspensions often show secondary coagulation or the presence of a clot. This does not occur with washed cell suspensions or when inactivated sera are used for the tests.

False agglutination by umbilical cord serum: Wiener observed that some cord sera produce a phenomenon resembling true agglutination. While testing a series of cord sera with A and B blood cell suspensions by the open slide method, he found that when the slide was tilted back and forth the cells came together in clumps but that these clumps broke up again if the slide was allowed to remain at rest. The process could be repeated indefinitely. It was demonstrated that Wharton's jelly from the umbilical cord was responsible for the phenomenon.

THE "BLIND" TEST

In 1952 Wiener described the advantages of using his so-called "blind" test.[28] He stated that it is often difficult to make one's readings entirely objective so that subconsciously, for example, one tends to shake the tubes a little harder when a negative reaction is anticipated. Such pitfalls can be avoided only by taking the readings blind, that is, one investigator sets up the tests while a different worker reads the reactions without knowing the exact nature of the mixture which is being examined for clumping. If the observations are really objective and not due to artifacts, they should be reproducible when the tests are made on a different day with the tubes arranged in a different order, so as to avoid the possibility of subconscious bias in the person making the readings.

CONTROLS

As in other laboratory tests, the use of controls in testing unknown blood is imperative. Even when taking such precautions as using no antisera beyond their expiration date, the blind test, and the best technic possible, mistakes can be made, and controls, when properly carried out, will prevent errors which could result in a transfusion reaction or death. These controls may be made simultaneously with the tests or they may be made just prior to testing the unknown bloods. When, because of the nature of the test, controls cannot be made, using the "blind" technic and making the tests in duplicate will help prevent mistakes.

ISOHEMOLYSIS

Certain unheated blood sera, when mixed with incompatible blood cells, will dissolve the cells instead of causing agglutination. This reaction occurs between sera of human blood and human blood cells and is not to be confused with hemolysis of certain blood cells by specific amboceptor sera. This reaction is due to isohemolysins normally present in the sera and is not caused by the isoagglutinins normally found in human sera. Thus it is not unusual for the serum of group O to hemolyze the blood cells of group A or even B or AB. The sera of group AB individuals do not contain isohemolysins. In blood grouping work, hemolysis must be considered equivalent to agglutination. Usually agglutination of the cells occurs first, followed by hemolysis. This is not necessarily true, for we have frequently observed the dissolving of erythrocytes without preliminary agglutination. In one instance a group B serum caused hemolysis of both A_1 and A_2 cells without first agglutinating them when the serum was unheated. After inactivation this same serum gave a titer of 80 units against the A_1 cells but required 10 min. to agglutinate the A_2 cells.

The drop of blood in which isohemolysis occurs can be observed in the process of clearing even by macroscopic examination. The orange-colored cloudy suspension will clear and take on a reddish cast. Observation under a microscope often will disclose some erythrocytes not hemolyzed.

Isohemolysis can be prevented by inactivating the serum at 56° C. for 30 min. to destroy the natural complement.

Isohemolysis is important because it may mask isoagglutination, and, if unnoticed, may be mistaken for a negative reaction and lead to incompatible blood transfusions. It is overcome in the usual grouping test by inactivating A and B antisera.

Chapter 73

The technic of blood grouping

ADDINE G. ERSKINE

GENERAL CONSIDERATIONS

Strict adherence to all details is mandatory in blood grouping technic. All glassware must be scrupulously clean and dry. Whenever possible, the use of expendable equipment is recommended. Soda straws are often used as a substitute for droppers. Expendable glass droppers (Fig. 468) are available from a number of manufacturers. Expendable slides are not necessary but are available if desired. When wax ring slides are used, the slides must be clean, fat-free, and dry before the rings are made. Such slides should be used only once. When the welled slides (Fig. 469) are used, they must be washed first by hand, then in running water, and then thoroughly dried. Ceramic slides (Figs. 470 and 471) are useful and may be used over and over, provided all traces of blood or blood products are removed from the slides. These, too, should be washed in running tap water and then dried before use. It is best to have a large container of water at hand into which the slides may be placed until ready to be washed.

Droppers should be soaked in water and then washed in running water to make sure that all blood products have been removed, if they are to be used again for blood grouping tests. Pipets must be thoroughly rinsed and then washed, preferably in a pipet washing device. If no such device is available, the pipets should be allowed to soak in a liter cylinder, then rinsed with distilled water, and dried in an oven.

All antisera must be stored in a refrigerator at 2°-5° C., when not in use. They must not be permitted to stand at room temperature unless needed at that time. Never use outdated testing reagents.

Blood to be tested may be kept refrigerated

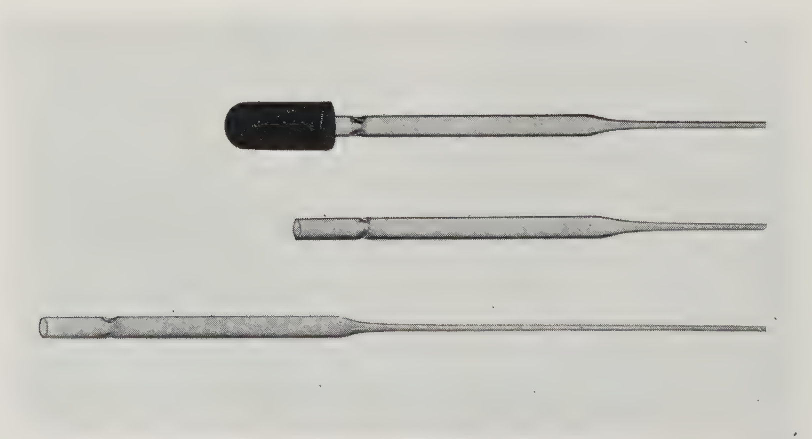

Fig. 468. diSPo-pipets. (Courtesy Scientific Products, Division of American Hospital Supply Corp., Evanston, Ill.)

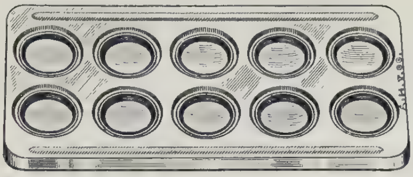

Fig. 469. Ten-welled slide for blood grouping. (Courtesy Arthur H. Thomas Co., Philadelphia, Pa.)

until ready for use. It warms to room temperature during the testing process.

Saline must be fresh, that is, preferably not more than 1 wk. old. Physiologic saline, 0.85% NaCl in distilled water, is used as the diluent in most of the tests. It should be filtered but need not necessarily be sterile. Chemical cleanliness is more important than sterility unless the diluted specimens are to be kept for some time in a refrigerator or unless the diluted blood is to be injected into animals or sent some distance from the laboratory.

Reagents: The following **testing sera** are needed for complete blood grouping tests for transfusions, including sensitivity testing for Rh-Hr antibodies, the A-B-O groups and M-N types, the antiglobulin (Coombs) test, and conglutination tests. All sera used for blood grouping work must meet the requirements for standards of potency (high titer) of the National Institutes of Health (NIH).*

1. Anti-**A** serum
2. Anti-**B** serum
3. Anti-**A**$_1$ serum (absorbed B or anti-**A**$_1$ Lectin)
4. Anti-**M** serum
5. Anti-**N** serum
6. Coombs serum (antihuman globulin)
7. 30% Bovine albumin
8. Anti-**Rh**$_0$ conglutinating (slide) serum
9. Anti-**Rh**$_0'$ conglutinating (slide) serum
10. Anti-**Rh**$_0''$ conglutinating (slide) serum
11. Anti-**hr**$'$ conglutinating (slide) serum
12. Anti-**hr**$''$ conglutinating (slide) serum
13. Anti-**Rh**$_0$ saline agglutinating (tube) serum
14. Anti-**rh**$'$ saline agglutinating (tube) serum†
15. Anti-**rh**$''$ saline agglutinating (tube) serum†
16. Anti-**hr**$'$ saline agglutinating (tube) serum†
17. Anti-**hr**$''$ saline agglutinating (tube) serum†
18. Witebsky group A and group B specific substances

The following **cell suspensions** must be prepared daily.* They are usable for 24 hr. Standard reference cell reagents, groups A_1 and B (human), are available from several sources.† These are specially prepared human blood cells containing a formula that eliminates hemolytic activity. They may be used as control cells or as the testing reagent when performing blood group tests on blood serum. In the latter case the serum need not be inactivated. If kept refrigerated, the cells maintain maximum reactivity for at least 3 wk. Control tests must be made using known anti-**A** and anti-**B** sera to make sure the cells have retained their activity. Most of the manufacturers add a dye as an additional precaution to prevent mix-ups. However, all laboratory workers should read labels carefully before use and should not depend on dyes in selecting their reagents. Before use, the cells should be thoroughly mixed in their respective containers.

Cell panels are also available for Rh-Hr testing. These are different red cell suspensions of group O blood tested for specific antigens. When the test cells are not purchased, the technician may prepare them in the laboratory. Prepare both saline-suspended untreated and trypsinated or ficinated cells of the various blood antigens for antibody tests, as follows:

Group O Rh_zRh_0
Group O Rh_1Rh_1
Group O Rh_2rh
Group O rh′rh
Group O rh″rh
Group O rh
Group A_1
Group B

The laboratory may prepare its own cells after testing individuals to determine the exact antigen on the cells; for example, group A_1 cells are obtained from an individual of group A_1, etc.

Additional reagents needed are as follows:

Trypsin, Difco 1:250, or ficin
Physiologic (0.85%) saline
Phosphate buffer, pH 7.41, M/15*

For the enzyme treatment of cells, some manufacturers now have available an acid solution of trypsin in Sørensen buffer.† This

---

*In a small laboratory, if all the cells are not available, use group O Rh_z, O rh, A_1, and B cells.

†Certified Blood Donor Service, Inc., New York, N. Y.; Knickerbocker Biosales, Inc., New York, N. Y.; Hyland Laboratories, Los Angeles, Calif.

*Eimer & Amend or other brand.

†Certified Blood Donor Service, Inc., Jamaica, L. I., N. Y.

may be used in place of the method outlined on p. 1463.

The use of ficinated cells has supplanted trypsinated cells in many laboratories.*

Equipment†:

1. Microscope containing a scanning lens, 32 mm. 0.10 strain-free. If this is not available, simply remove the front lens attachment from the low-power objective of a microscope and use the remaining lens system.
2. Electrically controlled water bath, which should be kept covered at all times.
3. An angle centrifuge (Figs. 473 and 474).‡
4. Racks for small tubes.§
5. Viewing box (Figs. 476 and 477).
6. A Brewer automatic pipetting machine is excellent but not absolutely essential.
7. Plain glass slides, 3 × 2 in.
8. 10-cell Boerner slides, 57 × 180 mm.‖ Fig. 469.
9. Ceramic 12-ring slides, containing baked-on red enamel rings (Figs. 470 and 471).
10. Wooden applicators.
11. Capillary or expendable droppers, and rubber bulbs.
12. Soda straws to use in place of droppers (or in addition to droppers).
13. Gauze pads, 3 × 3 in., 12 ply.
14. Red wax pencil.
15. Blue wax pencil.
16. Cover glasses, ⅞ in. square.
17. Tubes: 4 × ½ in.; 3 × ½ in.; 7.5 cm. × 8 mm.; B-D Vacutainer tubes for collecting specimens of blood.
18. Boerner electric rotating apparatus (Fig. 478).
19. Containers, about 250 ml. capacity, of different shapes, for holding saline and waste saline during the blood grouping tests.

Other reagents:

Preparation of saline: 0.85% NaCl. Strict chemical cleanliness is more important than absolute sterility in blood grouping serology.

Special anticoagulant for blood grouping:

Ammonium oxalate	3 gm.
Potassium oxalate	2 gm.
Distilled water	100 ml.

1. Put 0.2 ml. in the **bottom** of each tube. Dry in an oven.
2. For use, add 4.8 ml. venous blood and mix

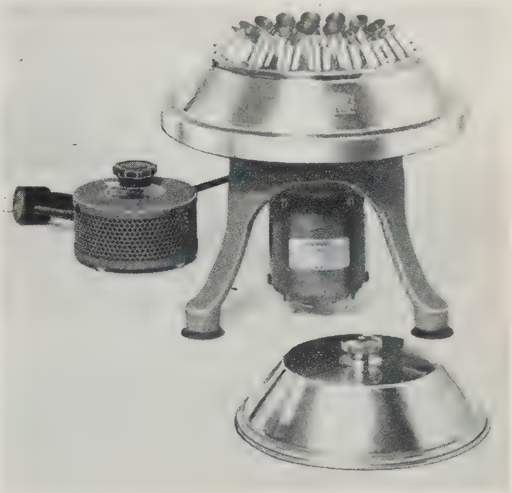

Fig. 473. Servall M, medium angle centrifuge. (Courtesy Ivan Sorvall, Inc., Norwalk, Conn.)

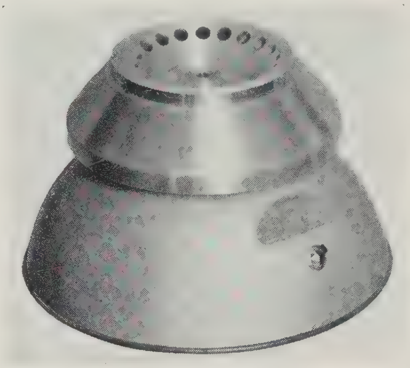

Fig. 474. Comet centrifuge. (Courtesy Phillips-Drucker, Astoria, Ore.)

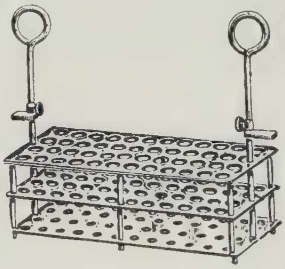

Fig. 475. Adjustable suspension test tube rack with handles, for small tubes used in blood grouping. (Courtesy Standard Scientific Supply Corp., New York, N. Y.)

---

*Ficin is manufactured by Nutritional Biochemical, Cleveland, Ohio, and may be obtained from Fisher Scientific, Pittsburgh, Pa.

†The list of equipment used here was compiled from that used in the laboratory of Dr. Lester J. Unger in New York City (New York University Medical Center Blood Bank).

‡That made by Ivan Sorvall, New York, N. Y.; 27-tubed head, with 18 holders in the outer circle and 9 on the inner, is excellent. The Comet by Phillips-Drucker, Astoria, Ore., is also recommended.

§We recommend those made by Standard Scientific Corp., Catalog No. 95222, with 4 rows of 10 holes per row. The top and middle sections have ⅝ in. holes, whereas the bottom of the rack has small (5/16 in.) holes.

by inverting about 20 times to keep the blood from clotting. An excess of oxalate interferes with Rh testing, at times resulting in false negative results.

For smaller amounts of blood, use the following formula:

Ammonium oxalate . . .	1.2 gm.
Potassium oxalate	0.8 gm.
Distilled water	100 ml.

1. Place 0.1 ml. in the **bottom** of each tube and dry by gentle heat in a dry heat oven. Use 1 ml. of blood and proceed as above.

EDTA anticoagulant: The sodium and potassium salts of ethylenediamine tetraacetic acid, known as EDTA-S or EDTA-P, act as anticoagulants by forming nonionized calcium salts, thereby preventing the coagulation of blood. The dipotassium salt is recommended, although either may be used. EDTA is also known as Versene or Sequestrene.

1. Make a 0.5% aqueous solution by dissolving 0.5 gm. in 100 ml. distilled water. This solution contains 5 mg./ml.
2. For use place 0.2 ml. or 4 drops 0.5% solution in a small test tube and dry in an oven at 90°-100° C. In some tests the anticoagulant may be used in liquid form. Use the dry anticoagulant for blood grouping.
3. Add 1 ml. blood to the tube containing 1 mg. dry anticoagulant and mix by inverting 5 or 6 times. If larger quantities of blood are required, use a correspondingly larger quantity of the anticoagulant.

EDTA-P is available in 5 mg. tablets.* For use, place 1 tablet in a small tube, add 1 drop distilled water, then add 5 ml. venous blood, and mix by inverting 5 or 6 times.

Preparation of plasma or serum:

1. For plasma, take blood in the special anticoagulant or in EDTA.
2. Mix to prevent clotting.
3. Centrifuge or allow to stand until the cells settle.

Remove enough plasma for cross-matching tests, sensitivity testing, and any other work required. Serum is preferred to plasma for these tests.

Whenever possible, use serum, prepared in the usual manner from clotted blood. Leave enough serum on the clot to resuspend the cells (50% cells, 50% serum) for the protein-media (whole blood) tests. (See below and also Fig. 479.)

---

*Cambridge Chemical Products, Inc., Dearborn, Mich.

Preparation of 2% or 3% cell suspension in physiologic saline (unknown cells):

1. Place about 1 ml. saline in a Kahn tube (3 × ½ in.).
2. Dip a straw into the cells left after removal of the plasma or serum, and add the cells to the saline, mixing in and out of the straw until a 2% or 3% suspension is obtained. This is judged by the color (tomato juice).
3. If clotted blood has been submitted, loosen the clot with a wooden applicator, centrifuge, remove the serum, use some of the cells shaken from the clot to make the saline suspension. Wash once in saline and resuspend to a 2% concentration with saline. Take care that no small clots remain in the cell suspension, since these might give a false appearance of clumping in the tests.
4. Another method of making a cell suspension from clotted blood is to dip a wooden applicator stick into the clot, mix around, and transfer the cells (which adhere to the stick) to saline in a small tube. Again, take care that no small clots remain in the saline suspension.

Preparation of control cell suspensions:

Untreated saline-suspended cells:

1. Prepare cell suspensions as outlined for the preparation of 2% or 3% cell suspension in physiologic saline.
2. Centrifuge to pack cells.
3. Remove supernatant saline.
4. Shake tubes to loosen cells.
5. Add saline to a 2% or 3% suspension (color of tomato juice) or 1 drop packed cells plus 30-49 drops saline. This is referred to as washing once with saline. Heavier suspensions are made for some tests.

Trypsinated saline-suspended cells: Trypsin must be prepared daily. Use Difco trypsin, 1:250. Use phosphate buffer solution, pH 7.41, M/15.*

1. Put a small amount of trypsin (about ¼ in. in a Wassermann tube) into a small tube, 5 × ½ in.
2. Add enough phosphate buffer to make a supersaturated solution.
3. Centrifuge. Remove the supernatant fluid and place it in another tube.
4. Wash a saline suspension of desired cells 4 times in saline.
5. Pack after the last washing by centrifuging; then remove the supernatant fluid.
6. To 9 drops packed washed cells add 1 drop freshly prepared trypsin.
7. Shake and place in a water bath at 37° C. for 1 hr., shaking every 15 min. while in the water bath.
8. Wash once with saline. (Add saline, centrifuge, and remove supernatant fluid.)
9. Resuspend to 5% concentration in saline, 1 drop concentrated cells plus 19 drops saline.

If kept refrigerated, trypsinated-saline suspended cells can be kept for 1 or 2 days. If some hemolysis occurs, wash once with saline and resuspend cells in fresh saline.

Ficinated-saline suspended cells:

1. Prepare a saline suspension of cells, wash twice with saline, and after the second washing centrifuge and remove the supernatant saline.
2. Prepare a 1% solution of ficin in phosphate buffer, pH 7.41, M/15: Place 0.1 gm. ficin in a Wassermann tube, and add 9.9 ml. phosphate buffer pH 7.41. Stopper and mix. This must **not** be a supersaturated solution. **Take care not to spill on the hands or splash into the eyes.** When the ficin has dissolved, centrifuge immediately to pack any undesirable particles or detritus and use the supernatant liquid.

If kept refrigerated, the ficin solution is useful for 5-6 days. If it is used often in the laboratory, it should be prepared at least twice a week.

3. Place 9 drops packed washed cells in a Wassermann tube.
4. Add 1 drop 1% ficin prepared as above.
5. Mix thoroughly and place in a water bath at 37° C. for 1 hr., shaking at intervals of 10-15 min. to make sure that all the cells are coated with the enzyme.
6. Fill the tube with saline and mix.
7. Centrifuge to pack the cells.
8. Remove the supernatant saline. This constitutes one washing.
9. Resuspend the cells to a 5% suspension.

These are enzyme-treated cells which are used in sensitivity testing and in any test for detection of univalent antibodies in the serum.

Enzyme-treated cells may be used for several days if kept refrigerated.

Rapid method of preparing ficinated cells—Wiener: The reagents, phosphate buffer, and 1% ficin are the same as those for ficinated-saline suspended cells.

1. Prepare a 3-5% suspension of the cells, wash twice with saline (centrifuge, remove supernatant saline, replace with a large volume of saline, and centrifuge; remove and discard the supernatant saline after the last washing).
2. Resuspend to a 3-5% suspension in saline.
3. Dilute the ficin solution 1:5 with saline, 1 part ficin solution to 4 parts saline.
4. Place 1 drop of the twice washed cells in a small Kahn tube and add 1 drop diluted ficin solution.
5. Mix by shaking and place in a water bath at 37° C. for 15 min.
6. Wash once with saline and remove and discard the supernatant fluid. This leaves 1 drop ficinated red blood cells in the tube.

Cells prepared in this manner are now ready to be tested with anti-**Rh**^{A}, anti-**hr′** serum, etc.

When the test calls for 2 drops of cells, use 2 drops of cells plus 1 drop diluted ficin solution and proceed as above.

When time is an important factor, it is best to use the rapid method of preparing ficinated cells for detecting unknown antibodies and for autoantibody tests on patients.

---

*Eimer & Amend or other brand.

For routine work, group A_1, group B, group O (Rh_zRh_o*) cells are used; for titrations, group O Rh_1Rh_1, group O Rh_2rh, group O rh′rh, group O rh″rh, group O rh, or specific panel cells. See p. 1522.

Preparation of whole blood—protein media cells suspended in their own plasma (C_{50}), 50% suspension:

1. After centrifuging whole oxalated blood, remove part of the plasma until there are equal parts of plasma and cells.
2. Shake to resuspend the cells.

Whole blood is used for slide Rh testing, both with unknown and control blood, and for testing for A-B-O groups by the rapid slide method. Whole blood is not recommended for A-B-O tests.

Using droppers to maintain a standard drop: In order to maintain standard drops throughout a test and also to save time and equipment, the following method, as suggested by Unger, can be used:

1. Have 3 containers, approximately 250 ml. capacity, each of a different shape so as not to confuse them. One is for saline for use in the test, one is for rinsing saline, and one is for discarded saline, cells, and plasma.
2. Discharge material left in the dropper into the waste container, wiping the outside of the dropper with a gauze pad.
3. With the bulb still squeezed, pick up a dropperful of rinsing saline and discharge it into the waste container, and continue squeezing the bulb.
4. Wipe the outside of the dropper, and, still squeezing the dropper, pick up another dropperful of rinsing saline, discharge it into the waste container, and repeat 5 or 6 times. Be sure to wipe the outside of the dropper.
5. With the bulb still squeezed so as not to admit any material from the dropper into the clean saline, pick up a dropperful of saline from the saline for use, and use what is needed, discharging the excess into the waste container. Always hold the dropper at the same angle when measuring drops for a test. Do not admit bubbles from a dropper, for this would result in less than a full drop.
6. If handling serum or plasma by this method, discharge excess remaining serum or plasma from the dropper into the waste container and not back into the original specimen.

Preparation of slides for blood grouping, Rh testing, and cross matching:

Wax ring slides: Wax ring slides may be used. These are prepared as for the Kline test. Prepare the slides by cleaning thoroughly to render them fat-free and make wax rings with the usual contrivance furnished by the manufacturer, using hot melted paraffin to make the circles on the slide. The capacity of each ring is about 0.05 ml., so that small drops of serum and cell suspensions should be used. By using a tray that can hold 3 of the paraffin ring slides, as many as 36 tests can be performed at one time.

Boerner micro test slides: The Boerner micro test slides (Fig. 469) are an improvement over the wax ring slides. These test slides are 88 × 58 × 2 mm., with rounded corners, and have 10 mold-pressed, raised rings, 15 mm. top diameter, in 2 rows each, numbered consecutively from 1 to 10. The bottoms of the cells are flat and slightly rounded at the periphery, to prevent capillary flow around the outer edge and to ensure thorough shaking of the drop. They also permit rapid macroscopic and microscopic examination. Although designed for the Boerner-Jones-Lukens microflocculation test, the slides are satisfactory for blood grouping procedures.

Ceramic ring slides: These slides are also available from a number of manufacturers (Figs. 470 and 471). The ceramic rings are baked on the slides so that the slides may be used over and over.

When using whole blood (protein media), prepare slides by drawing a large oval with a red wax pencil, using a heavy line. Dimensions of the oval are 1½ × ¾ in. Ceramic ring slides are also available for these tests.

Electric rotating apparatus: Blood grouping tests are facilitated by using the Boerner electric rotating apparatus (Fig. 478) when using the open slide method. This apparatus provides perfect rotation of the slides. There is an automatic cut-off timing device with speed control rheostat and motor with worm reduction gear and driving mechanism that rotates the platform in a horizontal plane so that it circles an area ¾ in. in diameter to simulate hand rotation.

When testing for blood factors not usually searched for in routine procedures, other antisera and equipment are needed. These are listed with the individual tests.

Caution: When the antisera are not in use, they must be kept refrigerated.

Always protect the testing sera against bacterial contamination.

All work should be read by at least 2 technicians, without access to the records of each other. If there is any discrepancy in the results, the tests should be made again.

The cell suspensions used for the day's work should be prepared fresh daily at the same time, preferably by the same technician.

ROUTINE BLOOD GROUPING TESTS MADE ON PATIENTS AND DONORS (Figs. 479-482)

Tests other than those routinely used are described throughout the section.

1. Test for A-B-O group of both patient's and donor's cells (use donor's cells even though previously tested in the blood bank), using a 2% or 3% suspension of cells in saline against known anti-**A** and anti-**B** sera.

---

*Agglutinated by all 5 standard antisera: anti-**rh′**, anti-**rh″**, anti-$\mathbf{Rh_o}$, anti-**hr′**, and anti-**hr″**.

Fig. 482. Tests on patient and donor.

2. At the same time, run controls on the antisera, using known group A$_1$ and group B cells (preferably but not necessarily type rh), 2% or 3% suspension in saline. The anti-**A** serum must cause agglutination of the A cells but not the B cells, and the anti-**B** serum must cause agglutination of the B cells but not the A cells.
3. Test the serum (or plasma) of both patient and donor against known group A$_1$ and group B cells suspended in saline. If isohemolysis occurs, inactivate the serum, cool to room temperature, and repeat the tests. If the results of this test differ from the results in step 1, repeat both tests, using a different set of known antisera to test the cell suspensions of patient and donor and different known A$_1$ and B cells to test their sera.
4. For further confirmation, test the whole blood of both patient and donor, using anti-**A** and anti-**B** sera, with the open slide method. This step is sometimes omitted from the routine procedure.
5. Subgroup all bloods belonging to groups A and AB by testing a saline suspension of cells against either absorbed B serum or anti-**A**$_1$ Lectin. Run suitable controls.
6. Test the **patient's** whole blood for the **Rh**$_o$ factor by the slide agglutination test, using anti-**Rh**$_o$ conglutinating (slide) serum. If the result is negative, consider the patient Rh-**negative** (even though there might be other Rh factors present), and use only **Rh-negative donor blood** for the transfusion. When possible proceed to step 8.
7. Test the **donor**'s whole blood against anti-**Rh**$_o$, anti-**Rh**$_o'$, and anti-**Rh**$_o''$ conglutinating (slide) sera.* If the blood gives a positive reaction with anti-**Rh**$_o$, all 3 tests will be positive. If the blood is negative with anti-**Rh**$_o$ serum but positive with either of the other 2 or with both, the donor must be considered as Rh-positive, and in such cases **do not give this blood to an Rh-negative patient.** If blood bank blood is used and tube tests have been made for the specific Rh factors, it is possible to find type rh (triple Rh-negative) donor blood. Any donor blood containing any of the Rh factors is unsafe for injection into an Rh-negative patient.
8. If the patient is Rh-negative by the slide test, and it is necessary to determine the exact Rh type, perform the Rh tube test, using 2% or 3% washed cell suspension in saline against known anti-Rh saline-agglutinating (tube) sera. Test for **Rh**$_o$, **rh'**, and **rh''**, as well as the Rh$_o$ variant ($\mathfrak{R}$**h**$_o$). If all these tests are negative, the patient is type rh (triple Rh-negative) and is assumed to be **hr'** and **hr''** positive. (For possible exceptions, refer to pp. 1501 and 1502.)
9. Cross match (a) the donor's cells against the patient's serum and (b) the patient's cells against the donor's serum, using saline-sus-

---

*These antisera are discussed on p. 1514.

pended cells, incubating in a water bath, reading macroscopically and microscopically. If no agglutination is evident on microscopic examination, wash the cells and proceed with the antiglobulin test on the cell sediment. See step 11 below. If any agglutination appears, reject the donor.

10. Perform the open slide protein media (Unger) cross-matching test by using (a) donor's whole blood against patient's serum (fortified with albumin) and (b) patient's whole blood against donor's serum (fortified with albumin).
11. The conglutinin method of cross matching (Wiener) may be substituted for step 10 or used in conjunction with it.
12. At the same time that the cross-matching tests are made, make an Rh sensitivity test, using the patient's serum against group O Rh_zRh_o cells (cells that are agglutinated by anti-**Rh**$_o$, anti-**rh**′, anti-rh″, anti-**hr**′, anti-**hr**″ sera). Panel cells may be used. Perform these tests using (a) untreated, saline-suspended cells and (b) trypsinated or ficinated cells suspended in saline.
13. Similar sensitivity tests should be made on the donor's serum at the same time that tests are made on the patient's serum.
14. Test the patient's serum for evidence of autoantibodies. If desired, also test the donor's serum at the same time. The ficinated cell technic is used for this test. Use the patient's serum with the patient's cells and the donor's serum against the donor's cells.
15. If any of the cross-matching tests show positive results, reject the donor.
16. If the sensitivity tests or autoantibody tests on the donor's serum show positive results, reject the donor for all time.
17. If the patient's serum shows evidence of Rh-Hr antibodies or of autoantibodies, make suitable reports to the director of the laboratory or blood bank.
18. In all cases of pregnancy perform a sensitivity test on the mother's blood and, if positive, titrate for antibody concentration. Repeat the titration throughout the pregnancy as requested by the physician in charge.
19. In unexplained erythroblastosis fetalis, test the mother's serum for antibodies other than the Rh-Hr antibodies, as well as for specific Rh-Hr antibodies, and in the presence of an A-B-O incompatibility titrate for concentration of **A** and **B** antibodies, as well as for anti-C (of the A-B-O system). When the antibody cannot be identified, send the serum to a blood grouping serology specialist.

A-B-O SYSTEM

TESTING UNKNOWN CELLS TO DETERMINE BLOOD GROUPS

In testing for the A-B-O blood groups, at least 2 tests must be made on every specimen: (1) identification of the cells by use of anti-**A** and anti-**B** testing sera and (2) identification of the serum by use of known A_1 and B cells. In testing the cells, saline-suspended cells give clearest reactions. Whole blood is not recommended, although the method of testing whole blood is given below. Controls must be made whenever the unknown cells are to be tested.

Using saline-suspended cells

Controls

1. Have on hand glass slides containing 2 wax rings (Fig. 480).
2. Label the left side "A" cells and the right side "B" cells.
3. Label the first slide "anti-**A**" serum and the second slide "anti-**B**" serum.
4. Place 1 drop of A cell suspension (preferably A_2)* in the left-hand ring of each slide and 1 drop of group B cell suspension in the right-hand ring of each slide (see p. 1463 for preparation of cell suspensions).
5. Add 1 drop of anti-**A** serum to each ring of the first slide, and 1 drop of anti-**B** serum to each ring of the second slide. Take care that the tips of the droppers do not touch the cells.
6. Mix and rotate, examining macroscopically and microscopically under the low power, without the Abbé condenser, at the end of 5 min. If high-titer antisera are not available, wait a total of 8 min. before taking the initial reading. The use of any but high-titer antisera may lead to errors and therefore is not recommended.
7. Do not apply heat during performance of the tests.
8. Examine for agglutination or lack of agglutination. Agglutination is a positive reaction, and lack of agglutination is negative. Add a drop of saline to each ring, mix, and rotate thoroughly; then take a final reading under the microscope.

The results expected in the controls are given in Table 297.

Table 297. *Results expected in controls on anti-***A** *and anti-***B** *sera*

	"A" cell suspension	*"B" cell suspension*
Anti-**A** serum	+ (Agglutination within 45 sec.-4 min.)*	− (No agglutination)
Anti-**B** serum	− (No agglutination)	+ (Agglutination within 45 sec.-3 min.)*

*High-titer antisera usually cause clumping within 10 sec.

Agglutination must be +++S, and lack of agglutination must not be doubtful (see description below and on p. 1455). Anti-**A** serum must agglutinate the A cells but not the

---

*More weakly reactive cells are used to show sera are potent.

B, whereas the anti-**B** serum must agglutinate the B cells but not the A.

If the proper results are obtained, grouping tests of the cells of the donor and the recipient may be undertaken, using these anti-**A** and anti-**B** sera. If agglutination does not take place properly or if the agglutinated masses are small, the antiserum is not usable. If there is no clear negative reaction, the antisera may not be used. In such cases discard the antisera and replace with new reagents, repeating the controls and the tests.

Actual blood grouping test using saline-suspended cells

1. Using a slide with 2 wax rings, label the left side "anti-A" and the right side "anti-B." Place the individual's name or laboratory number in the center of the slide for identification (Fig. 482).
2. Place a drop of the unknown cells in each ring.
3. Add 1 drop of anti-**A** serum to the left side and 1 drop of anti-**B** serum to the right side. Take care that the tips of the droppers do not come into contact with the cell suspensions. The antisera must not be contaminated in any manner. When the dropper is removed, hold the vial in a slanting position. When the antiserum is not in use, replace in a refrigerator.
4. Mix and rotate, examining macroscopically and microscopically (under low power without the condenser). Record a positive reaction whenever it occurs, but wait 5 min. before recording a negative. At the end of 5 min. add a drop of saline to each ring, rotate thoroughly to mix, and read again. Record agglutination as a positive reaction and lack of agglutination as a negative reaction. If there is any doubt about the reaction, repeat the test.

Some authors advocate mixing the contents of each ring with a separate toothpick or wooden applicator before rotating. If this technic is followed, take care to use a fresh applicator for each drop.

Do not apply heat. The action of the isoagglutinins is not enhanced by heat, and heat might actually interfere with the reaction.

Agglutination occurs as brick-red clumping of the cells, the clumps being completely separate from each other. Lack of agglutination is simply the homogeneous suspension of the cells as they appear when suspended in saline. Do not confuse settling of the cells and rouleaux formation of the red cells with true agglutination.

True agglutination is not affected by the addition of saline, whereas rouleaux are broken up with the addition of saline. See p. 1456 for a discussion of false reactions. Avoid working in drafts or where cold or warm air currents can blow over the open slides.

Determine the blood group by consulting Table 298.

Results of this test must be confirmed by testing the serum of the same individual against known A_1 and B cells as on p. 1469.

Table 298. *Identification of blood groups, using unknown cells*

*Unknown cells plus anti-**A** serum*	*Unknown cells plus anti-**B** serum*	*Group*
−	−	O
+	−	A
−	+	B
+	+	AB

− = no agglutination; + = agglutination.

Using cells suspended 50% in their own plasma (whole blood)

Controls

1. Prepare slides as described under the actual test below (Fig. 480).
2. Label the slides A cells + anti-**A**, B cells + anti-**A**, A cells + anti-**B**, and B cells + anti-**B**. Refer to Table 299.
3. Place about ½ drop of known A whole blood on the slides labeled "A" cells, and the same quantity of B whole blood on the slides labeled "B" cells.
4. Add 2 drops of anti-**A** serum to each slide labeled "anti-A" and 2 drops of anti-**B** serum to each slide labeled "anti-**B**."
5. Mix and spread each with a separate wooden applicator.
6. After sufficient time has elapsed for a reaction to take place, examine over a lighted viewing box (**not** preheated) for evidences of clumping. Add a drop of saline to each ring and permit it to run down through the drop of blood and serum mixture. Read after the addition of the saline. A final reading should not be taken in less than 5 min., and the blood must not be heated during that time.

Table 299. *Controls on anti-**A** and anti-**B** sera, using whole blood*

Slide	
1	Group A whole blood + anti-**A** serum
2	Group B whole blood + anti-**A** serum

4	Group B whole blood + anti-**B** serum

Table 300. *Test of unknown whole blood for A-B-O group*

Slide	
1	Unknown whole blood + anti-**A** serum
2	Unknown whole blood + anti-**B** serum

These controls are used when whole blood is to be tested as in the method following.

The reactions should be the same as those in Table 297; a positive reaction should occur within 1 min. Do not read microscopically.

Actual test

1. Prepare slides, 3 × 2 in., by making red wax oval rings 1½ × ¾ in., 2 such rings on each slide. See Table 300.
2. Label one ring "anti-A" and the other, "anti-B."
3. Label with the name or laboratory number of the individual being tested.
4. Place the whole blood to be tested in each ring by just touching the slide with the wet straw so that only a fraction of a drop is placed on the slide.
5. Add 2 drops of anti-**A** serum (of very high titer) to its proper ring and 2 drops of high titer anti-**B** serum to its proper ring.
6. Mix each ring thoroughly, and spread each with a different wooden applicator.
7. Place on a viewing box and tip downward but do not heat the box. Allow to remain on the box for 5 min., rocking it back and forth occasionally. At the end of 5 min. turn on the light and read for clumping or lack of clumping.
8. With the box tipped downward add a drop of saline to the top of each ring and let it run down into the test. If rouleaux are present, the saline will break them up, but true agglutination will remain unaffected.
9. Determine the blood group by consulting Table 298.

If the results using the whole blood and the cell suspensions are the same, proceed with the test in which the plasma or serum is used as the unknown. If the results are different in the 2 tests, an error has been made, and the tests must be repeated.

The use of whole blood to determine the A-B-O groups is not recommended because the ratio of red cells to the antiserum is quite critical, and mistakes can be made easily when too much whole blood is used.

TESTING UNKNOWN SERUM OR PLASMA TO DETERMINE BLOOD GROUPS

This is a very important confirmatory test. It serves as a control over the results obtained when testing unknown cells. It is not recommended for use by itself to establish blood group of an unknown. When serum is being tested, it is not necessary to wash the A and B control cells, but these cell suspensions should be washed if plasma is used as the unknown.

In order to determine the blood group using serum or plasma as the unknown, it is necessary to have at hand cell suspensions in saline of known groups A_1 and B bloods, preferably but not necessarily type rh, suspended to 2% or 3% concentration.

If time permits, inactivate the serum at 56° C. for 30 min. to destroy complement and prevent subsequent hemolysis if the serum contains an isohemolysin. If an isohemolysin is present in a serum along with the corresponding isoagglutinin, the opposing cells begin to clump and then dissolve, and the reaction is difficult or at times impossible to read. Isohemolysins will not act except in the presence of complement, which is destroyed at 56° C. When the complement is destroyed, the isoagglutinin is unaffected, being thermostable, and the usual agglutination reaction takes place.

Actual test to determine blood group using unknown serum

1. Use a slide with 2 wax rings. Label the slide with the name or laboratory number of the unknown. Label "A cells" at the left side of the slide and "B cells" at the right side.
2. Place 1 drop of known A_1 cell suspension in the ring labeled "A cells" and 1 drop of the known B cell suspension in the ring labeled "B cells" (Fig. 482).
3. Add a large drop of the unknown serum (or plasma) to be tested to each ring.
4. Mix and rotate in the usual manner. Read a positive reaction as soon as it occurs, but do not take a final reading of a negative reaction until 8 min. have elapsed. Read all reactions both macroscopically and microscopically. Agglutination may be strong or weak, depending upon the concentration of antibodies in the unknown serum. Do not wait too long before reading, or surface drying takes place and pseudoagglutination may occur.
5. Add a drop of saline to each ring, mix again, and take a final reading under a microscope. Never permit the drops to dry.
6. Determine the blood group of the unknown by consulting Table 301.

Table 301. *Identification of blood groups using serum as the unknown*

A_1 cells plus unknown serum	*B cells plus unknown serum*	*Agglutinins in serum*	*Blood group*
+	+	Anti-**A** Anti-**B**	O
−	+	Anti-**B**	A
+	−	Anti-**A**	B
−	−	Neither	AB

Explanation: This is a test to determine anti-**A** and anti-**B** agglutinins in the unknown serum. Group O serum contains both anti-**A**, which agglutinates A cells, and anti-**B**, which agglutinates B cells. Group A serum contains anti-**B**, which agglutinates B cells but not A. Group B serum contains anti-**A**, which agglutinates A cells but not B. Group AB serum contains neither anti-**A** nor anti-**B** agglutinins and therefore cannot agglutinate either A or B cells.

If the results in this test differ from those obtained when testing the unknown cells against anti-**A** and anti-**B** sera, that is, if a different blood group is shown, repeat both tests but use different antisera and different control cell suspensions.

Caution: It has been noted by many workers that the anti-**A** and anti-**B** agglutinins in group O sera are not necessarily present in the same degree of potency in a single serum. Thus, when testing group O serum, the ring containing A_1 cells might show marked agglutination while the ring containing B cells might show but slight agglutination, or vice versa. In cases of subgroups, notably in subgroup A_2 or A_2B, the agglutinin content of the serum might be so exceptionally low that a false negative reaction could result. When, after repeated tests, using different cell suspensions as controls and different antisera for the tests against the unknown cells, the results of tests on the blood cells and blood serum of the same individual seem to give different blood grouping results, it is advisable to send the blood to a serology expert for further tests.

SUBGROUPS OF GROUPS A AND AB

Von Dungern and Hirszfeld[31] first called attention to the fact that when a group B serum was absorbed with certain group A bloods until it lost the power of agglutinating the absorbing blood, the serum still agglutinated most other bloods of group A and group AB. They suggested a possible subdivision of groups A and AB. In 1923 this was further emphasized by Coca and Klein[32] and resulted in the recognition of the fact that there are subgroups of A and AB, namely, A_1 and A_2 and A_1B and A_2B. Today other subgroups are recognized: A_3, A_4, A_5, and C_A (also called A_0 or A_x). These are divisions of agglutinogen A. In other words, in the sera of group B and group O individuals there are agglutinins that act on the agglutinogen A. According to the common concept this agglutinin is a single entity designated anti-**A**. Actually, the so-called alpha (α) or anti-**A** agglutinin is composed of a number of qualitatively different fractions, of which there are 2 main varieties: (1) anti-**A** agglutinin proper, reacting with both agglutinogens A_1 and A_2 with approximately equal intensity, and (2) agglutinin anti-A_1, which reacts with agglutinogen A_1 but practically not at all with agglutinogen A_2. Different group B and O sera contain these 2 agglutinin fractions in varying quantities and proportions.[33] Two different group B sera which react with A_1 cells at approximately the same titer may have different titers when tested against A_2 cells. If, for instance, such sera contain very much anti-$\mathbf{A}_1$ and very little of the common anti-**A** agglutinin, there might be a titer of 40 for A_1 cells and a titer of only 5 for A_2 cells. On the other hand, another serum which contains a large proportion of common anti-A agglutinin might have a titer of 20-40 for A_2 cells even though the titer for A_1 cells is no greater than that of the first serum. In some cases group B serum may react distinctly on A_1 and practically not at all on A_2 cells. In the case of AB blood, the danger of using such sera, just described, for testing purposes is great, since the sensitivity of A_2 agglutinogen in this group is greatly diminished and such blood is readily mistaken for group B. It is for this reason that every group B serum (anti-**A**) used for testing purposes should be titrated against A_2 as well as A_1 cells. Since A_2 makes up approximately ¼ to ⅕ of all group A individuals among Caucasoids, it is clear that with weak anti-**A** testing sera 20-25% of group A individuals may be erroneously diagnosed as group O.

Landsteiner and Levine showed that the subgroups A_1 and A_2 are determined by heredity.

While, as has been shown, bloods containing agglutinogen A differ in their sensitivity to clumping by anti-**A** sera, bloods containing B agglutinogen give uniformly strong reactions with anti-**B** sera. A knowledge of the subgroups is essential to explain puzzling phenomena which are occasionally observed in blood grouping and cross-matching tests.

In order to obtain the subgroups of A and AB, it is necessary to have at hand at all times blood cells belonging to known subgroups A_1 and A_2, which are used as controls. The antiserum used for determining the subgroups is an anti-**A** serum which has been absorbed with A_2 cells to remove the common anti-**A** agglutinin, leaving behind anti-$\mathbf{A}_1$. This antiserum is called "absorbed B" serum or anti-$\mathbf{A}_1$ serum. An anti-$\mathbf{A}_1$ reagent has also been prepared from the seeds of the *Dolichos biflorus*. This reagent is called "anti-$\mathbf{A}_1$ Lectin."* It is a vegetable hemagglutinin which contains a stable lectin with suitable anti-A_1 reactivity. In the commercial product 0.1% sodium azide is added as a preservative. We have used the anti-A_1 Lectin concurrently with absorbed anti-A serum on the same blood specimens over a period of many months and find it as suitable for use as the absorbed B serum. It has the property, as does the absorbed B or anti-A_1 serum, of causing agglutination of cells of groups A_1 or A_1B, but it does not clump cells of subgroups A_2 or A_2B.

False positive reactions occur when there is a residual trace of common anti-A agglutinin in the absorbed serum. On the other hand, if absorption of the common anti-A agglutinin is overzealous, the anti-A_1 agglutinin is also considerably weakened, and the serum is worthless.

If subgrouping tests are performed at too low a temperature, as in a cold room during winter, the residual nonspecific anti-A agglutinin will cause clumping of A_2 as well as of A_1 blood.

If the mixtures are allowed to dry because of delay in taking readings at the end of the prescribed time, false positive reactions may result.

Newborn infants' bloods may show false negative reactions. It is best not to report a final subgrouping reading until the infant is at least 3 mo. old.

False negative reactions occur when the room temperature is too high.

Old blood suspensions are less sensitive than freshly made suspensions, and, if used, false negative reactions might result.

In order to safeguard the subgrouping procedure against error, proper controls must be made using known A_1 and A_2 cell suspensions against the anti-A_1 serum, as explained below.

Technic of subgrouping A and AB blood cells

Controls

The reagent used for subgrouping groups A and AB cells, as stated above, may be either absorbed anti-A serum or anti-A_1 Lectin. When using an absorbed serum, it is necessary to limit the time between making the test and reading the reactions, since such sera are often slightly underabsorbed and may give false positive reactions after a prolonged time period. In order to determine the **time element** as well as to make sure the reagent reacts as it should, controls must be made just prior to using the reagent, testing it against known A_1 and A_2 cell suspensions.

1. Prepare 2-3% suspensions of known groups A_1 and A_2 cells, respectively, in saline. When using anti-A_1 Lectin, use a 10% cell suspension.
2. Place a drop of known A_1 cells in a wax ring on a slide properly labeled and a drop of known A_2 cells in another ring also properly labeled.
3. Add to each drop of cells 1 drop of absorbed anti-A serum or anti-A_1 Lectin.
4. Rotate and observe under the low power of a microscope until agglutination takes place, recording the time required to agglutinate A_1 cells. The A_2 cells must remain unagglutinated for at least 10 min. If the serum is not completely absorbed, they may eventually be agglutinated by the antiserum.
5. Record the time the first small clumps appear in the A_2 cell suspension ring if they do appear before the 10 min. time limit. The test on the unknown cells must be read within the time limit set by the controls.

For example, the A_1 cells were clumped in 1½ min., while the A_2 cells remained in even suspension with no clumps for 10 min. Allow a 2 min. time as a safety factor and read the results on the bloods being tested within 8 min. If the unknowns show agglutination in less than 8 min., the results may be recorded as positive. The time element is established primarily for reading negative results.

Actual subgrouping test

Using absorbed anti-A serum

1. Place 1 drop of the unknown cell suspension on the glass slide containing one wax ring, labeled with the name or number of the unknown and the group letter (A or AB).
2. Add 1 drop of absorbed anti-A serum and rotate after mixing.
3. Read microscopically under the low power without a condenser.
4. Take periodic readings, but record a negative reaction only after the end of the time limit

Table 302. *Determining subgroup of group A cells*

A cells plus absorbed anti-A serum	*Subgroup*
+	A_1
−	A_2

Table 303. *Determining subgroup of group AB cells*

AB cells plus absorbed anti-A serum	*Subgroup*
+	A_1B
−	A_2B

---

*Hyland Laboratories, Los Angeles, Calif.

established by the controls. Record agglutination as positive as soon as it occurs.

If the cells have agglutinated, they are subgroup A_1 (or A_1B).

If they have not agglutinated, they are subgroup A_2 (or A_2B).

Tables 302 and 303 give these results in chart form.

Using anti-A_1 Lectin

Tube method:

1. Place 1 drop of anti-A_1 Lectin in a 10 × 75 mm. tube.
2. Add 1 drop of 2% cell suspension in saline.
3. Mix and centrifuge at 500-1000 r.p.m. for 1 min.
4. Read immediately after twirling the tube to dislodge the sedimented cells.

Subgroup A_1 or A_1B cells will remain in the original "button" as loosened by twirling. Subgroup A_2 or A_2B cells will form a smooth suspension.

Slide method:

1. Place 1 drop of anti-A_1 Lectin on a plain glass slide.
2. Add 1 drop of 10% suspension of cells in saline.
3. Mix and spread over an area of about 20 mm. diameter.
4. Tilt the slide from side to side and observe for macroscopic agglutination.

Clumping of A_1 or A_1B cells will be visible within 20 sec. and the reaction need not be observed for more than 1 min.

Cells of subgroup A_2 or A_2B will show no clumping during this period but may show a slight reaction if observed for a longer time.*

Agglutinogens A_3 and A_4

In 1935 Fischer and Hahn[34] reported the occurrence of rare individuals of group A whose blood gave only feeble reactions even with the most potent anti-**A** sera. Friedenreich, reporting on the same phenomenon, conceded that the weak reactivity of such bloods was due to a third sort of A agglutinogen, namely A_3. This agglutinogen A_3 gives rise to 2 additional subgroups in groups A and AB, subgroups A_3 and A_3B, respectively. These subgroups can be detected without any special method by their weak reactions with anti-**A** sera. A_3 blood, like A_2 blood, is agglutinated by sera containing anti-**A** isoagglutinin. Sera of group A_3 contain anti-**B** agglutinins just like ordinary group A sera, but, as in A_2 sera, anti-A_1 cold agglutinins may be present in these and in A_3B sera. The existence of A_3 receptor may account for certain errors in blood grouping.[35]

Wiener and Silverman[35] reported an interesting case belonging to subgroup A_3. Although this individual belonged to group A, the red cells showed weak and incomplete agglutination reactions with anti-**A** sera, both sera obtained from group B human beings and those prepared by immunizing rabbits with human A blood, in contrast to A_2 and A_1 cells which gave prompt and marked agglutination. Microscopic examination of the tests showed clumps on a background of many free cells. With weak anti-**A** sera the patient's blood might have failed to react. That she belonged to group A was further established by testing her serum against standard O, A_1, A_2, and B cells. With the B cells, prompt agglutination was obtained, demonstrating the presence of the anti-**B** agglutinin. No reaction occurred with O or A_2 blood cells, but a weak reaction occurred in the test with A_1 cells. This patient's serum contained, therefore, in addition to the anti-**B** agglutinin, an irregular agglutinin anti-$\mathbf{A}_1$. These observers therefore felt justified in placing this blood in the subgroup A_3.

An extremely rare A_4 blood group has been described by Gammelgaard and Marcussen.[36] There is a very weak reaction of the A_4 cells with anti-**A** sera. A further serologic characteristic is a reaction with certain group O sera and immune sera of rabbits, which is stronger than in group B sera. An irregular agglutinin for A blood cells was proved in the sera of 13 out of 15 cases. A_4 was found only once in routine examination of 60,000 blood samples. The presence of A_4 was proved in 24 persons of a family of 64 members. The importance of the A_4 group lies in a possible mistaken identification by reason of the very weak reaction, which is further lowered in combination with agglutinogen B as in group A_4B cells. The A_4 subgroup will rarely be revealed in routine serologic examinations of sera; therefore, in transfusions it may easily happen that blood of the A_4 group instead of O group is used. The A_4 group is comparable in its importance in legal medicine to that of the A_3 group, provided the hereditary process is clarified.

Factor C_A (A_o or A_x)—anti-C[37-41]*

In order to understand factor **C** of the A-B-O group, one must know the difference between an agglutinogen and a blood factor. An agglutinogen is a substance on the surface of the red cell. There are many agglutinogens on the human red cell shared by all members of the species and others that are type-specific, such as the A-B-O agglutinogens, the M-N-S-U agglutinogens, the Rh-Hr agglutinogens, etc. Agglutinogens are antigenic. When human cells are injected into a sensitive subject, antibodies are formed, which are capable of either clumping or lysing red cells of the same specificity as those injected to produce the antibodies. An agglutinogen can cause formation of and combine with more than one kind of antibody. The serologic specificities of agglutinogens defined by their corresponding antibodies are known as blood factors. Every agglutinogen has multiple blood factors that characterize it: e.g., agglutinogen M has the blood factors $\mathbf{M}_{i}$, $\mathbf{M}_{ii}$, $\mathbf{M}_{iii}$, etc.

---

*Directions from pamphlet supplied by Hyland Laboratories, Los Angeles, Calif.

*Do not confuse factor **C** of the A-B-O system, mentioned by Moss in 1910, with Fisher and Race's "C" of the Rh-Hr system.

Agglutinogen A has 2 principal blood factors, **A** and **C**, whereas agglutinogen B also has 2 main factors, **B** and **C**. Corresponding to the 3 blood factors, **A**, **B**, and **C**, there are 3 naturally occurring agglutinins, anti-**A**, anti-**B**, and anti-**C**. Thus the composition of the 4 blood groups can be summarized as in Table 304.

Table 304. *Composition of the 4 blood groups*

Blood groups	*Red blood cells*		*Serum isoantibodies*
	Agglutinogens	*Blood factors*	
O	*	*	Anti-**A**, anti-**B**, and anti-**C**
A	A	**A** and **C**	Anti-**B**
B	B	**B** and **C**	Anti-**A**
AB	A and B	**A**, **B**, and **C**	None

*"O" is now considered a blood factor. Agglutinogen O and factor **O** are omitted here for the sake of simplicity.

If group O serum is titrated for anti-**A** and anti-**B** and then absorbed with cells of group A until it loses its ability to cause agglutination of group A cells, there is usually appreciable reduction in the titer for B cells. Conversely, if group O serum is absorbed by group B cells until it no longer agglutinates group B cells, the titer is also markedly reduced for group A cells. If, however, one pools anti-**A** and anti-**B** sera instead of using group O serum for the titration of antibodies and then absorbs such pooled sera with A cells, the anti-**B** titer is not reduced; nor is the anti-**A** titer reduced if such sera are absorbed with B cells. It thus seems reasonable that group O serum contains a third agglutinin, anti-**C**, specific for a blood factor **C** shared by agglutinogens A and B.

Moreover, injections of group A blood into group O individuals often cause a rise in titer for group B cells as well as for group A cells; similarly, injections of group B blood into group O subjects may stimulate a rise in the titer for group A as well as for group B cells.

It is relatively easy to prepare high-titered anti-**A** immune rabbit sera free of the **C** antibody, but anti-**B** immune sera are generally of considerably lower titer and contain a good deal of anti-**C** which is difficult to remove by absorption. Thus, if antisera from immunized rabbits are used for blood grouping, many group A individuals will be incorrectly classified as group AB because of traces of the anti-**C** agglutinin in the anti-**B** reagent, which will clump both A and B cells.

It is now apparent that a **blood group C,** with an incidence of 1 in 60,000 individuals, has been identified. This group is called C_A (formerly A_o or A_x); the cells fail to clump when mixed with anti-**B** or anti-**A** sera, but they are agglutinated by most group O sera. In a case cited by Wiener[33] the red cells reacted as group O in tests carried out in the usual manner with anti-**A** and anti-**B** grouping sera, whereas the serum agglutinated all cells of groups A and B but not of group O. In addition, the cells were agglutinated by all group O sera. Group O sera contain not only anti-**A** and anti-**B** but the agglutinin anti-**C**, not present in the sera of other blood groups, which seems to prove that this blood belonged to rare blood group C. The serum of this individual contained both anti-**A** and anti-**B** agglutinins.

It must be remembered that blood factor **C** is shared by both agglutinogens A and B and is therefore found in the cells of groups A, B, and AB but not in group O cells. In A-B-O hemolytic disease (p. 1539) the mothers are almost always of group O. If one postulates that most cases of A-B-O hemolytic disease are due to sensitization to the **C** factor, this would account for the excess of group O mothers in that disease.

The peculiar properties of group C_A appear to be due to a predominance of factor **C** on the red cells. The anti-**A**, **B** serum contains considerable anti-**C** and is therefore suitable for detecting bloods of group C_A. Refer to p. 1475 for use of this serum.

Subgroup A_m

According to Landsteiner's rule for the A-B-O groups, those agglutinins are regularly present in the plasma for which the corresponding agglutinogens are absent from the red cells, except during the neonatal period. In cases of agammaglobulinemia, the absence of agglutinins is merely one manifestation of a disorder which affects antibody production in general.

Wiener and Gordon[42] described a patient whose red cells reacted as group O and whose serum agglutinated group B cells only but failed to clump group A cells, even those of subgroup A_1. The gamma globulin concentration in the patient's serum was normal or slightly above normal. In tests with potent anti-**A** serum, not only from immunized human beings but also from immunized rabbits, the patient's red cells failed to agglutinate, which would indicate absence of blood factor **A**. Both groups A_4 and C_A (A_0) were excluded by further tests. Tests on the saliva showed that it inhibited anti-**A** strongly but did not inhibit anti-**B**, demonstrating that the saliva contained A substance.

The findings resembled the A-B-O reactions in lower monkeys and gorillas. Tests on monkey saliva disclosed the same reactions as this patient's saliva, and tests on the monkey cells were like those of the patient. Because the blood of this patient gave reactions resembling those of lower monkeys, the subgroup has been given the designation "A_m."

The suppressor *y* gene

The suppressor *y* gene, a very rare occurrence, inhibits the expression of the **A** antigen on the red cells but not in the saliva when it is present in its homozygous form *yy*. According to W. Weiner and others,[43] the **A** antigen could not be demonstrated on the red cells except by absorption. Less than normal amounts of A substance were present in the saliva in the case they described.

Factors of agglutinogen B

B_i, B_{ii}, B_{iii} – B_3: Although A and B agglutinogens are often treated as simple substances, it is well known that each is characterized by multiple factors. Agglutinogen B has a number of blood factors designated $\mathbf{B_i}$, $\mathbf{B_{ii}}$, $\mathbf{B_{iii}}$, all apparently found in most human groups B and AB blood. Factor $\mathbf{B_i}$ is not present in rabbit cells, the rabbit having only $\mathbf{B_{ii}}$ and $\mathbf{B_{iii}}$. Agglutinogen B also has factor **C**, as explained on pp. 1472 and 1473.

In 1955 Moullec et al.[44] described an unusual case in which the erythrocytes reacted very weakly with anti-**B** serum and absorbed the anti-**B** poorly. Eluates from these cells demonstrated more anti-**B** activity than did eluates prepared from normal B cells. The gene responsible for these reactions was traced through 3 generations. The saliva showed the presence of O (H) substance but the complete absence of B substance.

Sussman et al.[45] reported a second example of an unusual B_3 gene. During routine preoperative blood grouping and cross matching for transfusion they found that the serum gave different blood group results from those given by the cells. The patient's cells had been grouped as O, but the serum contained only anti-**A** and no anti-**B** agglutinin. This blood appeared to be compatible with group O blood donors not only in the tests using saline-suspended cells but also with the antiglobulin and high protein methods as well.

The patient's cells were agglutinated in potent anti-**B** sera and several group O sera after several hours at 25° C., but the agglutinates were barely visible clumps of 5-10 cells surrounded by many unagglutinated cells. When ficinated cells were used in cross matching, the results showed incompatibility with "immune" O sera and some random group O sera against the patient's cells, but all group B sera and some random group O sera were compatible.

Neutralization studies showed that the serum contained no demonstrable B substance. Although the saliva contained O (H) substance, no B substance was present. This discovery of another B_3 individual indicates the importance of testing the serum against known cells routinely in all blood grouping.

The "Bombay" blood type: The Bombay blood type was described in 1952 by Bhende et al.[46] and in 1955 by Levine et al.[47] The characteristics of this blood presumably result from the action of a pair of modifying genes *Xx*. In its rare homozygous form *xx*, the expression of the antigen **B** on the red cell and in the saliva is completely inhibited. The red cells of this blood type are not agglutinated by anti-**A**, anti-**B**, or several varieties of anti-**O** (H).[45]

The weak B of Mäkelä and Mäkelä[48]: These authors described a weak **B** antigen found on the red cells in the presence of an antibody of **B**-like activity in the serum. The patient's B cells were not agglutinated by the anti-**B** in the serum.

B_w of Levine, Celano, and Griset[49]: The weak B antigen $\mathbf{B_w}$ reacted with antiserum to produce the "extremely weak agglutination seen in artificial mixtures of 99 parts of group O blood and 1 part of normal group B blood." Both B and O (H) substances were present in the saliva of those carriers of $\mathbf{B_w}$ who were secretors. The $\mathbf{B_w}$ antigen is apparently weaker than $\mathbf{B_3}$.

$\mathbf{B_x}$ of Yokoyama, Stacey, and Dunsford[50, 51]: $\mathbf{B_x}$ was originally investigated because of the unexpected absence of anti-**B** from the serum of a presumably group O person. $\mathbf{B_x}$ is much weaker than $\mathbf{B_3}$. It reacts almost exclusively with immune O (anti-**A** and anti-**B**) serum. Small amounts of **B** antigen are demonstrable by absorption and elution studies on the red cells. B substance is clearly demonstrable in the serum and both B and O (H) substances are present in the saliva of all carriers of $\mathbf{B_x}$ gene. According to Sussman et al.,[45] the $\mathbf{B_x}$ of Yokoyama seems most nearly comparable to the $\mathbf{A_m}$ described by Wiener and Gordon.[42]

USE OF ANTI-A,B SERUM*

Anti-**A,B** serum is used (1) as a screening reagent to detect group O individuals who are to be used as "universal donors" and (2) as a confirmatory reagent in blood grouping tests.

Anti-**A,B** sera are obtained from group O individuals whose blood sera contain both anti-**A** and anti-**B** agglutinins in high titer and of high avidity. The anti-**A,B** serum will cause agglutination of cells of groups A, B, and AB but not of group O. Since, as previously stated, agglutinogen A contains a number of subgroups and bloods of these subgroups tend to react weakly with ordinary anti-**A** testing serum, the anti-**A,B** serum, being of high titer and avidity, reacts readily with blood containing the agglutinogen A_2 as well as with A_1. It also reacts with blood cells of the other subgroups of A.

Technic of using anti-A,B serum

Prepare a 2% suspension in saline of the blood to be tested.

Make the tests either in tubes with 7-8 mm. inside diameter or on the open slide.

Tube test:

1. Mix 1 drop of anti-**A,B** serum with 1 drop of 2% cell suspension in a small tube.
2. Permit to remain at room temperature for 1 hr. or centrifuge for 1 min. at 500 r.p.m.
3. Report clumping as positive and lack of clumping as negative.

Slide test:

1. Place 1 drop of 2% cell suspension in a well of a blood grouping slide.
2. Add 1 drop of anti-**A,B** serum.
3. Rotate back and forth for 10 min.
4. Read microscopically and macroscopically for agglutination or lack of agglutination.

If no agglutination occurs, the blood belongs to group O. If clumping occurs, the blood is A, B, or AB. Consult Table 305.

Table 305. *Reactions of unknown cells with anti-***A,B** *serum*

Cells of group	*Anti-***A** *serum*	*Anti-***B** *serum*	*Anti-***A,B** *serum*
O	–	–	–
A	+	–	+
B	–	+	+
AB	+	+	+

Suitable controls should be made of the anti-**A,B** serum; that is, the antiserum should be tested against groups A_1, A_2, B, and O cells. The controls are made in a manner similar to the tests.

PREPARATION OF ANTI-A AND ANTI-B TESTING SERA

Preparation of sera

The testing sera must be of a high degree of potency (titer). It is a mistake to use testing sera that do not meet the standards of the National Institutes of Health (N.I.H.). It is a mistake to pool different lots of anti-**A** or anti-**B** sera and use them for testing purposes unless each of the pooled sera is of high titer and avidity. No anti-**A** serum should be used for testing purposes unless it will agglutinate group A_1 cells at a 1:256 dilution, group A_2 cells at a 1:128 dilution, group A_1B cells at a 1:128 dilution, and group A_2B cells at a 1:64 dilution. No anti-**B** serum should be used to test unknown blood cells unless it will agglutinate group B cells at a 1:256 dilution. These are the requirements of the N.I.H. Unless one uses great quantities of the testing sera, it is much better to purchase them already prepared and standardized. Be sure to examine for the expiration date, and use only those manufactured under special license, in order to avoid grave errors in blood grouping tests.

Select an individual (group A for anti-**B** serum; group B for anti-**A** serum) with a high titer serum and without Rh antibodies. Use sterile precautions throughout the procedure of obtaining and preparing the serum. Remove the blood by venous puncture, either with a sterile 20 ml. syringe or, if blood is desired in larger quantities, use the commercially available vacuum bottles without anticoagulant. If using the smaller quantity, eject the contents of the syringe, under sterile precautions, into a clean, dry, sterile 50 ml. Rockefeller tube and immediately cork. Label with the name of the person from whom derived, the group letter, and the titer. Allow the blood to clot with the tube in a slanting position. Loosen the clot by striking the tube against the palm of the hand, and centrifuge at high speed for 30 min.

---

*From a pamphlet by A. S. Wiener, New York, N. Y. By permission of Dr. Wiener.

Observing all sterile precautions, carefully remove the supernatant serum by means of a sterile dropper, placing it in a clean, dry, sterile tube labeled with the name of the person from whom derived, the group letter, and the titer.

Cork the tube immediately. Inactivate at 56° C. for 30 min. to destroy the natural complement to prevent subsequent hemolysis, and to kill any contaminating bacteria.

Transfer this serum with sterile precautions to sterile ampules and hermetically seal. Label with the name of the donor, the group letter, the titer, and the date. Store in a refrigerator.

Save enough of the serum to re-test before using. Test against groups A_1, A_2, A_1B, A_2B, and O cells, suspended in saline, and also use the whole blood. The anti-**A** serum must agglutinate the A_1, A_2, A_1B, and A_2B cells but not the B or O, whereas the anti-**B** serum must agglutinate the B, A_1B, and A_2B cells but not the A_1, A_2, or O cells. All positive reactions must be +++S and all negative reactions must be free of clumps. If any other results are obtained, the antiserum is not suitable for use as a testing reagent and must be discarded.

Titration of sera

It is necessary to titrate anti-**A** serum against A_1, A_2, A_1B, and A_2B cells, and anti-**B** serum against B cells, A_1B, and A_2B cells,* to avoid using antisera which are too weak for proper detection of the blood groups of unknown blood. Weakly reacting sera will give false negative results in the grouping tests, which may lead to serious transfusion reactions. Three examples of each group of cells should be used.

In all titrations, serial dilutions of each serum are made and each dilution is tested against the opposing cells. The reciprocal of the highest dilution of the serum that causes definite agglutination of its specific cells is called the titer. Thus, if the antiserum agglutinates the cells when it is diluted 1:256, the titer is 256. Many different methods of titrating sera have been proposed, but we prefer the method of Unger, which follows.

Making dilutions for titrations: The sera should be inactivated at 56° C. for 30 min. and allowed to cool to room temperature before dilution. Prepare serial dilutions of sera of 1:1 (undiluted) 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, 1:512, and any other dilution desired or needed.

Use racks that hold 10 tubes per row. Rack up tubes 7.5 cm. × 8 mm., 10 per row, one row for each type of cells used. If titrating anti-**A** serum, 4 rows will be needed. If titrating anti-**B** serum, only 1 row will be needed, unless it is titrated against A_1B cells and A_2B cells, when 3 rows will be needed. These are the **titration tubes.** Refer to Fig. 496 for set-up for titrations.

At the same time, rack up 2 rows of Kahn tubes, 10 per row. These are the **dilution tubes.**

Use serum, not plasma, for titrations.

Place the serum in the first tube of the front row of Kahn tubes (dilution rack). Be sure that all tubes are properly labeled.

In all the back row tubes of the **dilution rack,** add saline to fill the tubes. This will be used to rinse the dropper. There are now 2 rows of dilution tubes, the first row empty except for the first tube, which contains serum, and a back row of 10 tubes filled with saline.

Put 1 drop of undiluted serum to be tested into the first tube of each row of the **titration tubes.**

Carry 10 drops of serum from the first tube to the second tube in the front row of **dilution tubes.**

Rinse the dropper with all the saline in tube 1 of the back row of dilution tubes and remove the discarded saline tube from the rack. Wipe off the excess saline with a gauze pad.

Put 10 drops of clean saline, using the same dropper at the same angle, in each tube of the front row of **dilution tubes,** beginning with tube 2.

Use the same dropper throughout the procedure and hold it at the same angle.

Mix the contents of tube 2 thoroughly in and out of the dropper, taking care to avoid bubbles.

Put a drop of this 1:2 dilution of serum into the second tube of the **titration racks** and carry 10 drops to tube 3 of the **dilution tubes.**

Rinse the dropper with all the saline behind tube 2 and wipe off the excess with a gauze pad.

Mix the contents of tube 3 (1:4 dilution) of the dilution tubes thoroughly and carry 1 drop to tube 3 of each **titration row** and 10 drops to tube 4 of the Kahn tubes for **dilutions.**

Again rinse the dropper, using the saline in the tube behind tube 3 and continue the dilutions and dispersal of drops as before until all the dilutions have been made and the titration racks contain 1 drop of the respective dilution per tube: 1:1 in the first tube, 1:2 in the second, 1:4 in the third, 1:8 in the fourth, 1:16 in the fifth, etc. See Fig. 496.

Add 1 drop of the correct cells* suspended in saline to each tube:

A_1 cells in one row containing serially diluted anti-**A** serum

A_2 cells in one row containing serially diluted anti-**A** serum

A_1B cells in one row containing serially diluted anti-**A** serum

A_2B cells in one row containing serially diluted anti-**A** serum

Use the same dropper after rinsing thoroughly with saline as directed. This ensures the same size drop for both serum and cells.

Shake thoroughly and leave for 2 hr. at room temperature. Tip the rack so that the bottoms of the tubes are visible and take readings from the bottoms of the tubes. Negative reactions run down

---

*2% or 3% suspended in 0.85% saline (p. 1463).

*If anti-**B** (group A) serum is titrated against A_1B and A_2B, 3 rows of titration tubes will be needed.

Table 306. *Examples of titrations*

1:1	*1:2*	*1:4*	*1:8*	*1:16*	*1:32*	*1:64*	*1:128*	*1:256*	*1:512*	*Titer (units)**
++w	–	–	–	–	–	–	–	–	–	½
+++s	+++s	++w	+s	+w	–	–	–	–	–	16
+++s	+++s	+++s	+++s	+++s	+++w	+++w	++s	+w	±	256
+++s	+++w	+++w	++s	+	+w	–	–	–	–	32

*The titer (in units) is the reciprocal of the highest dilution of serum giving a 1 plus reaction.

in a pear-shaped formation. Agglutination reactions usually remain round.

Flick the tubes, gently spread the contents over the tube surface, and read under a scanning lens of a microscope. Or remove a small amount of sediment from each tube and examine under a microscope.

Reading results: It will be noted that the clumps of blood cells gradually become smaller as the serum becomes weaker. With some sera one dilution of serum may show strong agglutinating powers, whereas the next dilution shows a clear negative reaction. Report as 3 plus strong (+++S) any complete agglutination, that is, with no unagglutinated cells present. A 3 plus weak (+++W) reaction would be complete agglutination but with smaller clumps. A negative (−) reaction is absence of any signs of agglutination microscopically or macroscopically. Record reactions as +++S, +++W, ++S, ++W, +S, +W, ±, and −. The reciprocal of the last dilution in which there is definite agglutination (at least +W) is the titer.

Obviously, the first serum (Table 306) would be of no value for laboratory testing purposes. This blood would, however, yield ideal plasma because of the low isoagglutinin content. **Caution:** Even though a serum can be diluted and remain reactive, it is not useful for testing purposes unless it shows a +++S reaction when undiluted.

PREPARATION OF ABSORBED B (ANTI-A_1) SERUM

Observe all sterile precautions throughout the entire process. If the serum is contaminated, it will lose its agglutinating powers and will give false results.

Place a few ml. sterile 3.8% sodium citrate in a sterile 50 ml. Rockefeller tube and replace the cork immediately. Withdraw blood with a syringe from the vein of an individual of subgroup A_2 and add it with sterile precautions to the sodium citrate solution. It is best to pool the blood from a number of different group A_2 individuals.

Cork and mix well to prevent coagulation.

Centrifuge and wash 3 times with sterile 0.85% saline (p. 1463) and pack by centrifuging.

Discard the supernatant fluid after the last washing. These cells are the packed, washed, pooled group A_2 cells.

Place high titer group B (anti-A) serum, obtained under sterile precautions, in a 50 ml. sterile Rockefeller tube and inactivate at 56° C. for 30 min.

Add ⅓ to ¼ as much of the packed, washed, pooled group A_2 cells to the serum.

Cork and mix back and forth.

Allow the mixture to stand for 30 min. at room temperature, inverting occasionally; then centrifuge to separate the serum.

Remove and keep the supernatant fluid, which is absorbed B (anti-A_1) serum. It will usually be found that the recovered serum no longer reacts with group A_2 cells but still agglutinates group A_1 cells distinctly.

To test absorbed B (anti-A_1) serum

Have on hand a minimum of 3 known group A_1 and 3 known group A_2 cell suspensions derived from different individuals. These are prepared in the usual manner (p. 1463).

Place a drop of each cell suspension in a wax ring on a slide properly labeled and add a drop of absorbed B (anti-A_1) serum to each one.

Rotate and observe every 30 sec. under the low-power objective of a microscope until 5-10 min. have elapsed. A_1 cells should be agglutinated within 1 or 2 min., while the A_2 cells should not be agglutinated at the end of the 5-10 min. period.

If neither A_1 nor A_2 cells have been agglutinated, discard the serum. If the A_2 cells are agglutinated in less than 5 min., repeat the absorption, using fewer A_2 cells than during the preceding absorption period and reducing the time of absorption to guard against overabsorption. Test the serum against known A_1 and A_2 cells.

IRRADIATED BLOOD TYPING SERUM

With the advent of nuclear weapons and the common use of radioactive materials, a real possibility exists of exposure of medical biologicals to radiation. A study was made by Jamison to determine what change if any occurs when blood typing serum is exposed to ionizing radiation.[52]

Radiation causes coagulation and precipitation of protein in solution because of a denaturing process,[53] and this coagulation by radiation is irreversible. Changes have also been observed in surface tension and viscosity of protein solutions.[54]

Comparison of wet and dry typing sera irradiated at a dose level of 10,000 r with fresh nonirradiated typing serum revealed no change in the specificity of blood typing at the dose levels tested, and no delay was observed in the typing reaction. However, there did appear to be a slight acceleration in the rate of reaction of the Rh group with both wet and dry sera when the typing sera were exposed to 3000 r. Apparently blood-typing sera may be used after exposure to radiation in this dosage.

Rh TESTING

Before a cross-matching test is conducted, the blood of the patient must be tested to determine if it is Rh positive or Rh negative (usually for routine purposes determination of presence or absence of the **Rh**$_0$ factor is all that is required). Tests for the 3 principal Rh factors, **Rh**$_0$, **rh′**, and **rh″** are also made on the blood of the donor, and an Rh-negative donor is selected for the patient whose blood lacks the factor **Rh**$_0$. These tests are described on pp. 1514-1520.

TITRATION OF ANTI-C ("CROSS-REACTING ANTIBODY") IN GROUP O SERUM (USEFUL IN A-B-O ISOSENSITIZATION IN ERYTHROBLASTOSIS FETALIS)

Method of Jones et al.

Group O serum is characterized not only by the presence of anti-**A** and anti-**B** agglutinins but also by a third naturally occurring antibody, anti-**C** (p. 1473). As previously pointed out, absorption of group O serum by group A cells not only removes the anti-**A** agglutinins but also reduces the titer for group B cells; similarly, absorption with group B cells removes the anti-**B** agglutinins and reduces the titer for group A cells. Since both group A and B cells contain a mutual factor, "**C**," described by Moss in 1910, this reduction in titer of group O serum is due to removal of the naturally occurring anti-**C** of group O serum. In A-B-O hemolytic disease of the newborn it is the anti-**C** that coats the infant's cells.

Jones et al.[55] described a method of titration of group O serum for concentration of anti-**C** antibody, making use of the phenomenon of mixed agglutination of minor erythrocyte populations. If a suspension of group A red cells is diluted with a suspension of group O cells so that the concentration of group A cells is not greater than 1 part/500 parts of O cells, it is possible to sensitize the group A minor population cells with specific isoantibody, such as anti-**A**, without the occurrence of agglutination. If the suspension is washed to remove all free anti-**A**, addition of a further suspension of group A cells to the sensitized population mixture results in development of characteristic small agglutinates. Each of these agglutinates consists of an original sensitized A cell bound to the added or "detector" A cells by bivalent anti-**A** molecules. If one uses group O serum in place of anti-**A** serum to sensitize the group A minor population cells, specific mixed agglutinates will be formed not only on the addition of group A detector cells but also on the addition of group B detector cells. It thus appears that group O serum (but not group B serum) contains an antibody capable of uniting a group A cell to a group B cell.

The same type of experiment may be performed using group B cells instead of group A cells as the minor population and group A cells as the detector cells. Since group O serum contains both anti-**A** and anti-**B** in addition to anti-**C**, a group A minor population sensitized with group O serum will always be able to form mixed agglutinates with group A detector cells, and a group B minor population will also be able to form mixed agglutinates with a group B detector suspension.

The test consists of the attempted demonstration of the specific linkage of group A cells to group B cells through the medium of an antibody contained in group O serum. Those group O sera that have the power of linking A and B cells together are regarded as possessing anti-**C**, the cross-reacting antibody. The titration of this antibody is performed by determining the greatest dilution of serum at which this property can be demonstrated. As Jones et al. have pointed out, the titer is usually similar for both O (A) and O (B) population mixtures, although occasional examples of gross "asymmetry" are encountered.

It is possible that titrations for anti-**C** concentration in maternal serum may be useful in the prenatal diagnosis of erythroblastosis fetalis due to A-B-O incompatibility.

Cell suspensions: Prepare 5% suspensions of group A$_1$, group B, and group O cells by pipetting 2.5 ml. of twice-washed packed cells into separate 50 ml. volumetric flasks and diluting to 50 ml. with saline.

Population mixture O(A): Pipet 0.05 ml. of 5% group A cell suspension into a 25 ml. volumetric flask and dilute to 25 ml. with a 5% group O cell suspension.

Population mixture O(B): Pipet 0.05 ml. of 5% group B cell suspension into a 25 ml. volumetric flask and dilute to 25 ml. with 5% group O cell suspension. Invert both flasks repeatedly for at least 3 min.

Serum: Inactivate the serum to be tested at 56° C. for 20 min. Immediately before the test add the tetrasodium salt of ethylenediaminetetraacetic acid (EDTA) in a concentration of approximately 1 mg./ml. This suppresses anomalous mixed agglutinates, but the effect is reliable for only about 24 hr.

Isotonic EDTA-saline: Add EDTA to 0.9% sodium chloride solution in a concentration of 1 mg./ml.

Technic of the test:

1. Make 6 sets of serial 2-fold dilutions of the serum using EDTA-saline as the diluent, carrying out the dilutions to the tenth power (1:1024). See p. 1476 for correct method of preparing the diluted serum.
2. To each tube of the first 3 sets of dilutions add an equal volume of O(A) population mixture suspension.
3. To each tube of the second 3 sets of dilutions add an equal volume of the O(B) suspension. Refer to Table 307.

Table 307. *Cell population mixtures and added cells in Jones test*

Dilution set	*Population mixture*	*Group of added cells*
1	O(A)	A
2	O(A)	B
3	O(A)	O
4	O(B)	B
5	O(B)	A
6	O(B)	O

4. Mix by shaking and leave at room temperature for 15-20 min.
5. Wash the cell suspensions in all tubes 3 times in isotonic saline, taking care to avoid loss of cells. It is not necessary to use EDTA-saline for this step.
6. Restore to approximately the original volume.
7. Add equal volumes of group A, group B, and group O cell suspensions to each set of sensitized washed cells, respectively, A to the first series of dilutions, B to the second, and O to the third. Take care that the added cells are thoroughly interspersed in the population mixture by shaking and inversion. See Table 307.
8. Centrifuge the tubes at 250 g for 1 min.*
9. Gently but completely resuspend the cell deposit by inverting the tube.
10. Carry out the centrifugation and resuspension 3 times. Do not disturb the cell deposit after the final centrifugation until immediately prior to reading.

Reading results: Resuspend the cell deposit in sufficient saline to produce a convenient concentration of cells for observation in a hemacytometer chamber (about 0.2% concentration). Introduce the diluted suspension into the counting chamber and examine under a microscope for presence of characteristic agglutinates. The agglutinates are uniform spherical masses of cells about 20μ in diameter and occur with a frequency of about 2 per field.

The presence of typical mixed agglutinates in the suspension indicates a positive result. Absence of agglutinates is a negative result. There are generally fewer clumps in the last 2 tubes showing a positive result in the titration than in the suspensions exposed to more concentrated serum, but there is not the gradual diminution of clump frequency with progressive serum dilutions as seen in conventional agglutinin titrations. The end point of a mixed agglutination titration tends to be more sharply defined than the end point of an agglutinin titration.

The series of tubes to which group O detector cells were added constitute negative controls, and no agglutinates should be observed in those suspensions. If agglutinates are observed in the negative control tubes, this indicates lack of suppression of anomalous mixed agglutination or that the serum contains a specific or nonspecific agglutinin which is clumping the major population cells.

In this system, presence of anti-**C** in group O serum is revealed by formation of mixed agglutinates in those tubes in which a group B detector suspension has been added to an O(A) population mixture or in those tubes in which a group A detector suspension has been added to an O(B) population mixture. Addition of group A detector cells to an O (A) population mixture will always produce mixed agglutinates because of the almost invariable presence of anti-**A** in group O serum. Likewise those tubes in which group B detector cells are mixed with the O(B) population mixture should show mixed agglutinates.

The mixed agglutination titer of anti-**A** and anti-**B** in a group O serum will generally parallel the agglutinin titer. The titer of anti-**C** appears to bear only an approximate relationship to the agglutinin titers. Anti-**C** is more likely to be found in those group O sera having agglutinin titers for anti-**A** or anti-**B** over 256 and is less likely to be found when the agglutinin titer is below this level. According to Jones et al. tests of several hundred sera have not yet disclosed an instance of an anti-**C** titer in excess of those of anti-**A** or anti-**B**.

---

*Consult the manufacturer's speed and force table for the centrifuge used or apply the equation: $RCF = 0.00001118 \times N^2 \times R$, where RCF = centrifugal force × g, N = revolutions/min., R = rotating radius in cm. at the outer tip of the tube.

TITRATION OF ANTI-A AND ANTI-B IN SERUM FOR DETECTION OF ISOSENSITIZATION IN ERYTHROBLASTOSIS FETALIS

Method of Unger modified after Wiener et al.

In cases of erythroblastosis fetalis or in sensitization unexplained by the Rh-Hr factors, it is necessary at times to titrate anti-**A** and anti-**B** in the patient's serum. With ordinary methods of titration it is not possible to differentiate between natural and artificially produced anti-**A** and anti-**B** antibodies. The following method attempts to make the differentiation.

Reagents:

Acacia:

1. Dissolve 20 gm. acacia (gum arabic) and 2 gm. Na_2HPO_4 (dibasic sodium phosphate) in 180 ml. distilled water.
2. Autoclave at 10 lb. pressure for 10 min.
3. Use the supernatant fluid.

Cells: Use A_1rh cells suspended in saline for titrating anti-**A** in group O or group B serum. Use Brh cells for titrating anti-**B** in group O or group A serum.

Prepare the cells in the usual manner, wash once with saline, and resuspend to a 2 or 3% concentration in saline. See p. 1463.

Procedure:

Titration for bivalent antibodies:

1. Make serial dilutions in saline of the serum to be tested: 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, 1:512. See p. 1476 for exact technic.
2. Add 1 drop of the opposing cells to 1 drop of each dilution of serum. Carry out 2 titrations on group O serum, 1 using A_1rh and 1 using Brh cells.
3. Incubate in a water bath at 37° C. for 1 hr.
4. Examine the sediment macroscopically and under a scanning lens.
5. Report clumping as positive and lack of clumping as negative.
6. Record the result in each tube as the bivalent (agglutinating) antibody titer.

Acacia conglutination titer:

1. To each negative tube add 1 drop of the acacia solution.
2. Mix and incubate in a water bath at 37° C. for 1 hr.
3. Read as before. Report the results. This gives the acacia conglutination titer.

Titration for univalent antibodies:

1. At the same time run titrations on the same serum diluted 50% with Witebsky group specific substance (1:2).
2. Carry out the titrations exactly as directed above and report results in the same manner.

If there is a titer in this second set of tubes, the antibodies are due to isosensitization by A-B-O factors, since ordinarily Witebsky substance neutralizes bivalent anti-**A** and anti-**B** antibodies. Apparently it does not neutralize the univalent antibodies.

Examples: For examples, see Table 308.

Conclusions:

1. The titer for anti-**A** bivalent antibodies (Table 308) is 64. These are the naturally occurring antibodies.

2. The titer for anti-**A** univalent antibodies when acacia is used in the titration is 8, but there is no univalent antibody titer against saline-suspended untreated cells. These are the isoimmune antibodies.

3. The anti-**B** titer for bivalent antibodies is 128; when acacia (conglutinin) is used, it is 256.

4. The anti-**B** univalent antibody titer is 16 for untreated cells but 32 when acacia is added.

At birth, anti-**A** and anti-**B** are passively acquired by placental transfer from the mother. Anti-**A** and anti-**B** antibodies later

developed by the individual are generally of heterospecific origin. The titration described here is used to differentiate between bivalent and univalent antibodies. This patient has been isosensitized against A and B agglutinogens and has univalent antibodies in the blood. If this occurs in unexplained erythroblastosis fetalis, the individual is sensitized to A-B-O and not the Rh-Hr factors.

CROSS MATCHING

After the blood group and Rh type of the patient have been established, and a donor of the same blood group and Rh type has been tentatively selected, cross-matching tests must be made. That is to say, one must match the donor's cells with the patient's serum and the patient's cells with the donor's serum, and there must be no signs of agglutination of the red cells. It is well to make sensitivity tests for Rh-Hr antibodies and tests for autoagglutinins at the same time as the cross-matching tests are run. See p. 1484 for the methods.

Caution must be exercised in accepting blood grouping designations by other laboratories. Remember that the person making the transfusion is responsible for any accident that may happen; therefore, all donors and recipients must be regrouped or retyped when they appear for examination or transfusion, and every patient or donor must be re-examined before every transfusion. This is in no way intended to criticize the work of other laboratories but is simply a measure of precaution which each one must follow.

One procedure, which is mentioned only to be condemned, is to perform cross-matching tests **alone,** omitting blood grouping. From time to time it has been claimed by some that cross-matching tests preliminary to transfusions are superfluous. It was erroneously believed that if the A-B-O blood grouping tests were properly carried out on the blood of the patient and donor, and if the results showed them to be of the same blood group, there would be no danger of a transfusion reaction. Unger found this to be incorrect.[56] He was the first to report that occasionally the serum of a patient would clump the cells of a donor even though they both belonged to the same A-B-O blood group and that transfusion of such blood was followed by chills and fever, which he attributed to the observed incompatibility (intragroup transfusion reactions). He called the antibodies responsible for the intragroup incompatibility "minor" agglutinins to distinguish them from the anti-**A** and anti-**B** agglutinins. He used a 2% suspension of the cells in the individuals own plasma to carry out these cross-matching tests, although at that time it was customary to use only saline-suspended cells. He had unwittingly carried out the "conglutination" test and detected the univalent antibodies (blocking, incomplete antibodies), although he did not identify them. Some of these most likely were Rh antibodies.

With the development of blood banks there has been a great increase in the number of patients transfused and the number of transfusions given to the same patient. These repeated administrations of blood expose patients to a great variety of antigens, and they may become sensitized, since it is practically impossible to transfuse a patient with blood that is identical to his own with respect to all blood factors. There are probably hundreds of thousands of possible combinations of blood factors known today. Perhaps some day a complete blood grouping may become as distinctive as a thumbprint, as predicted by Karl Landsteiner.

Correct cross-matching results can be obtained only on bloods of the same group or subgroup: while one may match the cells of the so-called "universal donor," group O, with the serum of almost every other individual, the reverse gives incompatible results; that is, the serum of group O will agglutinate the cells of all other groups—A, B, and AB, but not O.

Since cross matching is not a test for Rh types, it is necessary to make preliminary Rh tests on both patient and prospective donors.

Cross-matching tests must be capable of detecting not only the incompatibilities in the A-B-O system but must also detect univalent and bivalent antibodies in the other blood group systems. For this reason cross matching using saline-suspended cells only, without supplementary tests, is now considered definitely inadequate protection for the patient.

Technic of cross matching

Cells and serum are needed from the patient and from each prospective donor. The donor's serum may be obtained from the pilot tube if bank blood is used. The cell suspension from the donor may also be made from the pilot tube by dipping an applicator stick into the clot, breaking the clot, and transferring to saline the cells that adhere to the stick. If whole blood is to be used, it may also be obtained from the pilot tube, by preparing a suspension of cells in an equal volume of serum. Any serum remaining from the pilot tube may be replaced if the blood is not to be used at that time.

Cell suspensions are made in saline, using a 2% concentration (p. 1463). For the Unger protein media test use whole blood, that is, cells suspended to 50% concentration in their own serum or plasma. Oxalated whole blood, centrifuged and leaving enough plasma after decanting to make 50% plasma and 50% cells, is the best method of preparation.

A **routine cross-matching test** includes the following:

1. Donor's cells + patient's serum.
2. Patient's cells + donor's serum.
3. Patient's cells + patient's serum (the autoantibody test).

In addition, **sensitivity testing of the patient's and donors' sera** is carried out to detect the presence of antibodies:

1. Patient's serum + group O mixed antigen cells, cells untreated and saline-suspended.
2. Patient's serum + group O mixed antigen cells ficinated and saline-suspended.
3. Donor's serum + group O mixed antigen cells untreated and saline-suspended.
4. Donor's serum + group O mixed antigen cells ficinated and saline-suspended.

Tube method of cross matching (Fig. 483)

Saline agglutination test:

1. Use tubes 4 × ½ in. for cross matching.
2. Place in a rack in 2 rows. Two tubes are required for cross-matching one donor's blood with one recipient's blood. If more than one donor is available, run the 2 tubes for each donor.
3. Label the front tubes "PS" for patient's serum, and the back tubes "DS" for donor's

serum. Identify each tube with the correct name or laboratory number.

4. Place 2 drops of patient's serum in the front tube (major).
5. Place 2 drops of donor's serum in the back tube (minor).
6. Add 2 drops of **donor's cells,** suspended in saline, to the front tube.
7. Add 2 drops of **patient's cells,** suspended in saline, to the back tube.
8. Mix each and incubate in a water bath at 37° C. for 30 min.
9. Centrifuge at 500 r.p.m. for 2 min. or 1000 r.p.m. for 1 min.
10. Pick up a small amount of the sediment from each tube with a straw or dropper and place on a properly labeled slide. Put a cover glass over each drop.
11. Examine under the low power of a microscope and search for clumping or lack of clumping.

If clumping of the cells has occurred, reject the donor. Examine the slides very carefully.

If the results are negative, examine the remaining contents of the tubes under a scanning lens of a microscope, by spreading the sediment the length of the tube with gentle rocking of the tube. If clumping appears, reject the donor.

This is a control over the slide reading.

If all the results are negative, proceed with the antiglobulin or Coombs test.

Coombs test (antiglobulin test): Coombs tests are made when the results in the cross-matching test (above) are negative.

1. Shake the tubes, add saline to the capacity of the tubes, centrifuge, and remove the supernatant saline. This is the first washing.
2. Shake the tubes, again add saline, and recentrifuge. Remove the supernatant saline and discard. This is the second washing.
3. Repeat for a third washing.
4. Remove the saline, turn the tubes upside down, and strike against a gauze pad to remove all traces of the saline from even the lip of the tube. Removal of all protein before the antiglobulin test (Coombs) is extremely important because if there is any protein left in the tube it interferes with and prevents an antiglobulin reaction.
5. Gently shake the tubes to loosen the cells.
6. Add 1 drop of antihuman globulin (Coombs serum) to each tube.
7. Mix.
8. Centrifuge at low speed, 500-1000 r.p.m., for 2 min.
9. Gently dislodge the sediment and read over a lighted viewing box and under a scanning lens of a microscope.

If any signs of clumping occur, reject the donor. See Table 309.

When the A-B-O compatibility has been proved, this test detects antibodies in the serum against one or more factors (other than A-B-O) of the blood it agglutinates.

Slide method of cross matching, using whole blood—protein media method, Unger (Fig. 483)

The autoantibody test is included in this cross-maching method.

1. Prepare 3 glass slides, 3 × 1 in., by drawing on each a large red wax oval ring the length of the slide and half the width.
2. Label the first slide "PS," the second slide "DS," and the third slide "PS" + "PC."

   Slide 1:

   2 drops of whole blood of donor
   +
   1 drop of patient's serum
   +
   1 drop of 30% bovine albumin*

   Slide 2:

   2 drops of whole blood of patient

ing it to run down through the specimen. Read for agglutination or lack of agglutination.

If either of the first 2 slides shows any evidence of agglutination, reject the donor. If there is no evidence of agglutination, the bloods are compatible and the donor's blood may be given to this patient.

If the autoantibody test is positive, that is, if the slide containing the patient's serum plus his own cells shows agglutination, the patient's blood contains autoantibodies. This must be reported immediately to the director of the laboratory. If this slide shows no agglutination, it may be considered a **negative control** over any positive reaction that may occur in the sensitivity test for antibodies in the patient's serum.

These slide tests are usually considered as screening tests; that is, if the results show incompatibility, there need be no further tests, but if the results are negative, then proceed with the tube test on pp. 1482 and 1484. These slide tests are never read microscopically.

Some laboratories prefer the conglutinin method of cross matching to the Coombs test. However, because the conglutination method cannot detect anti-**Fy**, the antiglobulin method must be used if an anti-**Fy** agglutinin is suspected.

Conglutinin method of cross matching

1. Carry out the test in 2 small Kahn tubes.
2. Place 1 drop of recipient's serum in a tube marked "RS."
3. Place 1 drop of donor's serum in a tube marked "DS."
4. Add 1 drop of 30% bovine albumin to each tube.
5. With an applicator stick, transfer enough cells from a clot of the donor's blood to make a 2% suspension of donor cells in the serum in the tube marked "RS."
6. Similarly, with an applicator stick transfer recipient cells to the serum in the tube marked "DS."
7. Incubate 3-5 min. at 37° C. in a water bath.
8. Centrifuge for 2 min. at 1000 r.p.m.
9. Dislodge the cell sediment very gently. Excessive shaking may break up agglutination. Observe for agglutination or lack of agglutination. If any agglutination is observed, reject the donor.

When A-B-O group compatibility is proved, agglutination in the tube marked "RS" indicates that the recipient is immunized against a blood factor of the donor cells. Further cross matching with other donor bloods must be carried out until blood is found that will not be agglutinated by the recipient's serum. Before testing with other donor bloods, the Rh type of the recipient must be carefully determined.

When Rh-positive recipients are immunized to Rh-positive blood belonging to a different Rh type and when Rh-negative recipients are erroneously designated Rh positive and isoimmunized, incompatibility with the donor blood may be detected by this method.

Routine test for cross matching, autoantibody testing, and detection of antibodies in serum (sensitivity testing), made simultaneously

When autoantibody and sensitivity tests are to be made simultaneously with cross-matching tests, 7 tubes are needed for each donor used with a specific patient.

In addition to 2% suspensions in saline of both the patient's and the donor's blood cells, saline suspensions of group O mixed antigen cells* and ficinated group O mixed antigen cells are needed.

Set up 7 tubes as follows for each donor used:

Tube 1: 2 drops of patient's serum + 2 drops of donor's cells (saline-suspended).

Tube 2: 2 drops of donor's serum + 2 drops of patient's cells (saline-suspended). Tubes 1 and 2 are for the cross-matching tests.

Tube 3: 2 drops of patient's serum + 2 drops of patient's cells (saline-suspended). Tube 3 is for the autoantibody test of the patient's serum.

Tube 4: 1 drop of patient's serum + 1 drop of group O mixed antigen cells, untreated and saline-suspended.

Tube 5: 1 drop of patient's serum + 1 drop of ficinated group O mixed antigen cells. If no mixed antigen cells are available, use group O type Rh_zRh_o cells, which have all the "standard" Rh-Hr blood factors.

Tube 6: 1 drop of donor's serum + 1 drop of group O mixed antigen cells, untreated and saline-suspended.

Tube 7: 1 drop of donor's serum + 1 drop of group O mixed antigen ficinated cells. Tubes 4 to 7 are for the sensitivity test (Rh-Hr and other antibodies in the serum).

Mix each tube separately, place in a rack, and put the rack in a water bath at 37° C. for 30 min.

Read macroscopically, observing the bottoms of the tubes. Positive reactions tend to remain in a "button," whereas in negative reactions the cells will run down when the tube is tipped and appear pear-shaped. Confirm all readings

---

*Cells having **Rh₀**, **rh′**, **rh″**, **hr′**, **hr″**, and other blood factors. These may be prepared by the laboratory or purchased from Certified Blood Donor Service, Inc., Jamaica, L. I., N. Y., or Knickerbocker Laboratories, New York, N. Y.

by examining under a scanning lens of a microscope.

If clumping occurs, reject the donor.

If no clumping occurs, wash the contents of the tubes 3 times with saline in the usual manner, and after the last washing remove all traces of saline.

Add a drop of antiglobulin serum (Coombs) to each tube, mix thoroughly, centrifuge at 500-1000 r.p.m. for 2 min., and read. If clumping now appears in tube 1 or 2 or in both, the bloods of the patient and donor are incompatible and the donor must be rejected. If no clumping occurs, the bloods are compatible and this donor may be used for this transfusion.

If clumping occurs in tube 3, the patient's serum contains autoantibodies, and this must be recorded and reported to the director of the laboratory.

If any of the sensitivity tests, tube 4, 5, 6, or 7, show positive reactions, proceed in the usual fashion by reporting to the physician in charge and to the director of the laboratory, particularly if the donor's serum shows antibodies. Such donors must be rejected for all time.

Note: Unger[57] suggests that cross-matching tests must be made using patient's serum + donor's ficinated cells and donor's serum + patient's ficinated cells, using the tube method of cross matching when the sensitivity tests are positive by the ficinated cell technic and negative by the other methods used. When the reactions in such tests are positive, it is always necessary to rule out the possibility of the presence of autoantibodies in the patient's serum. Under such circumstances use the patient's serum + his own ficinated cells.

Sensitivity tests may be made either with group O mixed antigen cells or with group O cells containing only one particular antigen, but such cells are not always at hand. The commercial mixed antigen cells contain all the Rh-Hr factors as well as the rare factor **Fy^a**, along with **M, N, Kell,** etc. Both untreated saline-suspended and ficinated cells are used.

Anti-**Fy^a** will not react with enzyme-treated cells so that saline-suspended untreated cells must always be used when searching for the **Duffy** factor.

The Le^a, K, or P tests are carried out in a refrigerator at 4° C. and also at room temperature. If the cells are not enzyme treated, the refrigerator temperature must be used for the **Le^a** factor. It is customary to use untreated saline-suspended cells when testing for **Le^a** and **P** factors.

When the mixed antigen cells have been suspended in saline and kept refrigerated overnight, they should be washed twice with saline when collected and once again before use. Those that are to be used as untreated saline-suspended cells are retained in one tube, and those that are to be enzyme treated are removed and transferred to another tube after the last centrifugation, when the supernatant saline has been discarded.

When ficinating cells, it is best to use a 3-5% suspension, the 5% being preferred. The method of ficinating cells is given on p. 1463.

Rapid ficinated cell technic for autoantibody test:

1. Place 2 drops of patient's washed cells in a small Kahn tube.
2. Add 1 drop of 1:5 ficin (1% solution diluted 1:5 with saline), p. 1463.
3. Mix thoroughly and place in a water bath for 15 min.
4. Wash once and resuspend the sedimented cells to a 4% suspension (1 or 2 drops of saline).
5. Add 2 drops of patient's serum, mix, and place in a water bath at 37° C. for 30 min.

Read under a scanning lens. If clumping has occurred, the serum contains an autoantibody. If no clumping occurs, no autoantibody is present. Some authors suggest that an antiglobulin test be made at this point after washing 3 times with saline, but such a test might give false positive reactions, and it is not recommended by Wiener.

SIMPLE BLOOD MATCHING

Simple blood matching is not recommended since it assumes that the donor belongs to a blood group different from that of the recipient. According to older ideas, group O was called the "universal donor," since it was believed that it was safe to transfuse any individual with group O blood. Group AB was called the "universal recipient" because it was believed that it was safe to give blood of any individual to an AB recipient. The rule was expressed as follows: All individuals could receive blood from members of their own group and from group O, and all individuals could give their blood to members of their own group and to group AB patients. This is not true, and following such a rule can lead to dangerous reactions and even death.

Simple blood matching is still used, but it is not recommended. The only use for simple matching is if the patient is to receive blood from a group O donor, the patient belonging to some group other than O. The test is made by mixing the patient's blood serum with the donor's cells, following any of the cross-matching tests previously described (tube or slide) and observing for signs of agglutination. If any clumps are observed, the donor is rejected.

POSTTRANSFUSION REACTION "WORK-UP"

After a transfusion reaction it is necessary to perform certain tests to discover the cause. A complete A-B-O, Rh-Hr re-examination must be made, and in some cases tests should be made for antibodies against antigens other than those in the Rh-Hr system.

Test for all of the Rh factors and subgroups (refer to section on Rh types) and make sensitivity tests on the patient's serum against cells containing all the known antigens, but do not use pooled or mixed antigen cells. Also test the donor's serum against each of the antigens.

In making these tests use both the untreated saline-suspended cells and the enzyme-treated (ficinated) cells, except when testing for the $\mathbf{Fy^a}$ factor, because the **Duffy** factor is active only in untreated cells.

Test the sera of all donors used for this patient prior to the reaction, as well as the present donor. No matter how many transfusions have been given to the patient prior to the reaction, tests should be made of the bloods of all donors if they are still available.

Test to determine whether or not the patient's serum agglutinates the patient's own cells, particularly if this is an Rh_o-positive woman. This test should be made prior to the transfusion. If it has not been made, use a sample of the blood taken before the transfusion.

Perform a routine cross-matching test on both the pretransfusion and the posttransfusion specimens of the patient's and donor's bloods. To this routine add the ficinated cell technic. Ficinated cells are not usually used in the routine cross-matching tests unless so specified, but they are used when there has been a transfusion reaction. This cross-matching test after the transfusion reaction must be made on both pretransfusion and posttransfusion specimens.

If suspicions exist as to antibodies other than Rh-Hr, make studies on the pretransfusion blood of the patient for antibodies against all the antigens available, such as $\mathbf{Fy^a}$, $\mathbf{Le^a}$, etc.

Test the patient's cells to determine if the patient lacks any of the known antigens. In this case use antisera containing all the known antibodies and test against the patient's cells. If the patient lacks any of the known antigens as determined by this test, determine to which one, if any, of these factors the patient has been sensitized. See p. 1523.

Recapitulation

Test the patient's cells, using known antisera of various specificities.

Test the patient's serum against all the known antigen cells. For example, in a retransfusion, in which the patient is type Rh_1Rh_1, if he has been transfused with blood of type Rh_2, he could have developed antibodies of the specificities anti-$\mathbf{rh''}$ and anti-$\mathbf{hr'}$.

There are some cases on record of M-N sensitization. Tests must be made for such sensitization by testing the patient's serum against a series of both M and N cells in suspension in saline.

Additional tests

A **cell survival test** should be made. If the transfused cells survive and the patient has no demonstrable antibody, the reaction was due to some cause other than an incompatible transfusion.

In some cases in which the patient has had a transfusion reaction and tests indicate that the reaction was not caused by incompatibility, the survival tests are made. Use cells taken from the patient after the transfusion to determine whether or not he has any of the transfused blood. For example, if he is type M and has been transfused with type N blood, as long as the type N cells are still demonstrable in his blood, these cells have survived in the patient's circulation. In order to test one's own accuracy in determining the presence of small quantities of cells of type N, for example, in a patient's type M blood, mix various specimens, using 10 parts of type M and 1 part of type N bloods, or 5 parts of M and 5 of N, etc.; make tests in the usual manner, using anti-**M** and anti-**N** sera. Clumps of cells on a background of unclumped cells can be found in these experiments, which resemble those found in the survival test.

In the example just given, if an Rh_1 patient (blood cells have factors $\mathbf{Rh_o}$ and $\mathbf{rh'}$) has been transfused with $\mathbf{Rh_2}$ blood (with factors $\mathbf{Rh_o}$ and $\mathbf{rh''}$), and $\mathbf{rh''}$ positive cells are found in the patient's blood following the transfusion, then any reaction that took place is probably **not** due to anti-$\mathbf{rh''}$ agglutinins. If such agglutinins had been present, they would have destroyed the rh″ cells.

Chapter 74

The Rh-Hr system

ADDINE G. ERSKINE

Rh-Hr NOMENCLATURE[58]

Two principal methods of designation of the Rh-Hr types are currently in use, the original Rh-Hr nomenclature and the C-D-E symbols. Significantly, the nomenclatures interpret the same set of observations differently, and so both cannot be correct. The Committee on Medicolegal Problems* has analyzed the available information in order to resolve this problem. Their conclusion is that the C-D-E notations "make no allowance for the difference between a blood factor and an agglutinogen, and make the tacit incorrect assumption that every agglutinogen has but a single corresponding antibody. . . . The Committee therefore recommends that the C-D-E notations for the Rh-Hr types be discarded, and that the original Rh-Hr nomenclature be retained as the sole nomenclature for this blood group system."

Rh-Hr GLOSSARY[59-61]

antigen Any substance which, when introduced into the body, usually by a parenteral route, stimulates the formation of specific reacting substances.

antibodies Specifically reacting substances, believed to be globulins in chemical structure, produced by the body in response to the introduction of an antigen.

red cell antibodies Substances occurring in blood serum which react with their specific antigen or agglutinogen which are found on the surface of red cells. Some antibodies clump cells, some coat cells, some lyse cells, etc.

agglutinogen A substance on the surface of red blood cells which, in combination with its specific antibody (agglutinin), results in clumping of the cells. Agglutinogens are named for the most important blood factor or factors that characterize them. For example, agglutinogen A is named for blood factor **A**, although it shares factor **C** with agglutinogen B. (Agglutinogen A has a factor $\mathbf{F_A}$, which it shares with sheep cells.)

anti-rhesus serum In the narrow sense, antiserum prepared in rabbits, guinea pigs, goats, and other animals in response to the injection of blood of rhesus monkeys. Thus the term applies to sera like the original experimental serum of Landsteiner and Wiener, which clumps the bloods of 85% of all Caucasoids. In the broad sense, the term has been applied to include also all related Rh and Hr antisera of human origin.

isoimmunization; isosensitization Production of antibodies by an individual of a species in response to stimulation by an antigen derived from a different member of the same species.

rhesus factors; Rh factors; Rh agglutinogens; Rh antigens Attributes of the surface of red blood cells responsible for the reactions with Rh antisera. Study of anti-Rh sera of human origin shows that there are a variety of factors related to the original rhesus factor of Landsteiner and Wiener. The one corresponding to the original factor is designated $\mathbf{Rh_o}$. Reciprocally related factors are termed Hr factors. There are 4 standard Rh factors: $\mathbf{Rh_o}$, **rh′**, **rh″**, and $\mathbf{rh^w}$. Four Hr factors have been found: **hr′**, **hr″**, **hr**, and $\mathbf{hr^S}$. There are also minor variants of the Rh-Hr factors.

rhesus antibodies, Rh antibodies The specific substances responsible for the reactions produced by anti-rhesus sera. The anti-rhesus (anti-Rh) sera prepared by immunizing animals with rhesus blood give parallel reactions with human bloods. The anti-rhesus (anti-Rh) sera of human origin are of 8 principal varieties. (1) Rh antibodies: anti-$\mathbf{Rh_o}$, anti-**rh′**, anti-**rh″**, and anti-$\mathbf{rh^w}$. (2) Hr antibodies: anti-**hr′**, anti-**hr″**, anti-**hr**, and anti-$\mathbf{hr^S}$.

$\mathbf{Rh_o}$ factor; standard Rh factor This is the original Rh blood factor that corresponds to the original rhesus factor of Landsteiner and Wiener and is present in the blood of approximately 85% of Caucasoids, 95% of Negroids, and almost 100%

---

*Medicolegal applications of blood grouping tests, supplementary report; A Report of the Committee on Medicolegal Problems, American Medical Association, prepared by A. S. Wiener, R. D. Owen, C. Stormont, and I. B. Wexler.[58]

of Mongoloids. It is the most antigenic of the Rh-Hr factors and therefore the most important clinically. More than 90% of cases of erythroblastosis fetalis and intragroup hemolytic transfusion reactions are due to this factor. When one speaks of the Rh factor, it usually is assumed that the **Rh**$_o$ factor is meant. The symbol for the factor **Rh**$_o$ is written with a large "R" to indicate that this is by far the most antigenic of the factors.

anti-Rh$_o$ serum; standard anti-Rh serum Serum specific for the **Rh**$_o$ factor. Only anti-**Rh**$_o$ serum of human origin is used for diagnostic purposes, since anti-rhesus immune animal serum clumps all blood specimens from newborn infants.

Rh testing Classifying human blood by tests with anti-**Rh**$_o$ serum alone. This divides all bloods into 2 types, Rh positive and Rh negative or, strictly speaking, **Rh**$_o$ positive and **Rh**$_o$ negative.

Hr factors Factors of Rh-Hr agglutinogens, which are responsible for reactions with Hr antisera. They are reciprocally related to the Rh factors, for which reason Levine first used the symbol "Hr" to indicate this relationship.

Hr sensitization The process of becoming sensitized to one or more of the Hr factors. When the Hr factor is not specified, it is usually the **hr**′ factor that is intended, since this is by far the most antigenic and the most important clinically.

Hr testing Examination of the blood with Hr antiserum. When the exact serum is not indicated, it is usually anti-**hr**′ serum that is intended.

Rh typing Classification of blood within 1 of the 8 Rh types with the aid of the 3 principal Rh antisera (see Table 310): anti-**Rh**$_o$, anti-**rh**′, and anti-**rh**″. There are 4 **Rh**$_o$-positive types and 4 **Rh**$_o$-negative types. For blood transfusions to all Rh-negative recipients, only type rh (Rh negative by the use of all 3 Rh antisera) should be given, to avoid isoimmunization due to injection of blood containing **rh**′ or **rh**″ factors. **All recipients who belong to types rh′ or rh″ must be given Rh-negative blood** (type rh*); since they lack the most antigenic of the Rh factors, **Rh**$_o$, they must not receive **Rh**$_o$-positive blood in a transfusion. **All donors who are Rh$_o$-negative but rh′- or rh″ positive must give their blood only to Rh-positive individuals.**

univalent antibodies One form in which antibodies of any given specificity may occur. Such antibodies tend to appear usually late in the course of immunization, are relatively thermostable, and readily pass through the intact placenta. In saline media univalent **Rh**$_o$ antibodies combine with and coat Rh-positive cells without clumping them. In protein media or in the presence of high-molecular colloids, univalent Rh antibodies clump cells containing the corresponding specific blood factor.

bivalent antibodies Another form in which antibodies of a given specificity may occur. Such antibodies usually are produced early in the course of immunization, are relatively thermolabile, and are effectively held back by the intact placental barrier. In saline as well as colloidal media they are capable of directly clumping cells possessing the corresponding specific antigen.

The differences between the bivalent and the univalent antibodies are summarized in Table 311.

agglutination Specific clumping of cells produced by bivalent antibodies.

conglutination Specific clumping of cells produced by the combined action of univalent antibodies and conglutinin.

conglutinin A colloidal aggregate of serum proteins which is adsorbed by cells that have been sensitized by their specific univalent antibody but not by cells that have not been sensitized and, after adsorption, causes the cells to stick together. Conglutinin is relatively thermostable but is sensitive to dilution with crystalline solutions, which causes it to dissociate into its constituent molecules. It is related to complement.

conglutinin substitutes Surface colloids, such as acacia, gelatin, dextran, and PVP, of complex molecular structure which can take the place of plasma in the conglutination test. Their ability to produce conglutination is due to their cohesive and adhesive properties, but they have the disadvantage of causing cells not coated by univalent antibodies to clump weakly, an undesirable quality not exhibited by natural or fortified conglutinin, and therefore it is not advisable to use these substitutes in routine practice.

fortified conglutinin Conglutinin that has been improved by the addition of the optimal amounts of albumin. Appropriate amounts (¼-⅓ its volume) of 30% albumin mixed with plasma contribute to the colloidal aggregates of protein in the plasma and thus enhance the conglutinin effect.

Rh antisera, anti-Rh sera, anti-rhesus sera Sera containing Rh or Hr antibodies, or both. These antibodies may occur singly, such as anti-**Rh**$_o$, anti-**rh**′, anti-**rh**″, anti-**rh**^{w}, anti-**hr**, anti-**hr**′, anti-**hr**″, and anti-**hr**^{S}, or in combinations, such as anti-**Rh**$_o$′, anti-**Rh**$_o$″, anti-**Rh**$_o$′″, anti-**rh**″,**hr**′, anti-**rh**′,**hr**″, and anti-**hr**″,**hr**^{S}.

Rh agglutinating serum Serum containing Rh antibodies predominately of the bivalent variety. Such antisera usually give best results by the so-called tube agglutination method in which dilute saline suspensions of red cells are mixed with the testing serum in small tubes and the reactions read after incubation at body temperature for 60-120 min.

Rh conglutinating serum Serum containing Rh antibodies predominately of the univalent variety. Such sera give best results by a variety of technics utilizing the principles of conglutination. For example, in the slide method a drop of serum is mixed with a drop of the whole, undiluted, oxalated blood being tested and the reaction read with the naked eye after the slide has been tilted back and forth for 1-2 min. over a warmed viewing box. Tube technics may also be used, for example, by using diluted suspensions of cells in plasma or albumin instead of saline or the indirect antiglobulin (Coombs) test. It is possible that all Rh antisera contain a mixture of both univalent and bivalent antibodies. If the univalent antibodies predominate, the antiserum must be

---

*If blood of the same rare type as that of the patient (rh′ for an rh′ patient, etc.) is available, it may be used.

Table 310. *Scheme of the 8 principal Rh blood types*

Blood containing factor **Rh$_o$** (**Rh$_o$** *positive*)				*Blood not containing factor* **Rh$_o$** (**Rh$_o$** *negative*)			
*Designation of types**	*Reactions with sera*			*Designation of types**	*Reactions with sera*		
	Anti-**rh′**	*Anti*-**rh″**	*Anti*-**Rh$_o$**		*Anti*-**rh′**	*Anti*-**rh″**	*Anti*-**Rh$_o$**
Rh$_o$	–	–	+	rh	–	–	–
Rh$_1$	+	–	+	rh′	+	–	–
Rh$_2$	–	+	+	rh″	–	+	–
Rh$_z$	+	+	+	rh$_y$	+	+	–

*Type Rh$_1$ contains the 2 principal factors, **Rh$_o$** and **rh′**, the name Rh$_1$ being short for Rh$_o'$; similarly Rh$_2$ is short for Rh$_o''$ and Rh$_z$ is short Rh$_o'$Rh$_o''$.

Table 311. *Properties of univalent and bivalent antibodies**

Characteristic	*Bivalent antibodies*	*Univalent antibodies*
Common name	Agglutinin, precipitin, agglutinating antibody, complete antibody	Glutinin, blocking antibody, conglutinating antibody, incomplete antibody
Usual time of appearance in course of immunization	Early	Late
Resistance to heating	Relatively thermolabile	Relatively thermostable
Reactions of **Rh$_o$** antibodies† in saline medium	Clumps cells by agglutination	Coats cells without clumping them—blocking reaction
Reactions of **Rh$_o$** antibodies in colloid medium	Clumps cells by agglutination	Clumps cells by conglutination
Reaction in presence of complement	Does not fix complement or lyse cells	Fixes complement and lyses cells if number of antigenic loci on cells surface is adequate; viz., lysis occurs in A-B-O tests but not in Rh-Hr, Kell, or Duffy tests
Behavior in mixed agglutination tests	Specific clumps are formed	Clumps contain more than one kind of cell
Opsonic effect	None	Positive in presence of complement
Chemical nature	Euglobulin; precipitated by sodium sulfate solutions of concentrations 13.5-17.4%	Pseudoglobulin; precipitated by sodium sulfate solutions of concentrations 17.4-21.5%
Electrophoretic behavior	Alpha and beta globulins	Gamma globulins
Sedimentation constant	17	7
Probable molecular weight	930,000	155,000
Diffusibility	Poor	Good
Behavior relative to placenta	Held back by intact placenta	Passes through placenta readily
Half-life	Probably 2 wk. or less	30-35 days
Role in syphilis	Flocculating antibody	Complement fixing antibody
Role in disease	Precipitating and agglutinating antibody	Protective antibody; antitoxin
Role in allergy	Sensitizing antibody (reagin)	Blocking antibody
Role in erythroblastosis	Not significant	Major

*From Wiener, A. S., and Wexler, J. B.: An Rh-Hr syllabus, the types and their applications, ed. 2, New York, 1963. Grune & Stratton, Inc.

†The in vitro reactions are somewhat different, depending on the antigen-antibody system.

used by a conglutination method; if bivalent antibodies predominate, the saline agglutination test may be used. If antiserum containing a suitably balanced mixture of **Rh**$_0$ agglutinating and blocking antibodies is titrated in saline medium, a prozone (p. 1521) may occur.

Rh sensitization; Rh immunization The act of becoming sensitized to the Rh factor. This may occur in an Rh-negative individual as a result of a transfusion or an injection of Rh-positive blood or as the result of a pregnancy with an Rh-positive fetus. Injections of small doses (2 ml.) of Rh-positive blood into Rh-negative individuals, at 4 mo. intervals, cause more than 40% of subjects to become immunized (for preparation of anti-Rh serum). When injections are continued, more than 75% of Rh-negative persons can be immunized. Clinically, 2 widely spaced transfusions of Rh-positive blood into Rh-negative persons are more likely to lead to Rh sensitization than multiple transfusions in a short space of time. Fetal blood enters the maternal circulation during the course of approximately 1 out of 3 normal pregnancies and 1 out of 3 deliveries. Once a person has been sensitized to the Rh factor, he remains so for the remainder of his life, although the titer gradually becomes weaker. When this occurs, a small injection of Rh-positive blood will stimulate a pronounced and sustained rise in antibody titer.

Rh agglutination test A test to detect Rh antibodies of the bivalent type. When applied to sera from Rh-negative individuals being tested for Rh sensitization, a drop of the patient's serum is mixed with a drop of 2% saline suspension of the standard Rh-positive red cells (group O), and the reactions are read after the mixture has been incubated at body temperature for 1 hr. See Fig. 484.

Rh blocking test A test to detect Rh antibodies of the univalent variety. This test is also known as the indirect test for univalent Rh antibodies. The patient's undiluted serum or diluted serum is first mixed with a 2% saline suspension of Rh-positive red cells as in the agglutination test. If no clumping occurs, a drop of good anti-**Rh**$_0$ agglutinating serum of moderate titer is added and the mixture incubated 1 or 2 hr. at body temperature. See Fig. 484. The failure of clumping to occur despite the addition of anti-**Rh**$_0$ agglutinating serum or a distinct weakening of the reaction indicates the presence of **Rh**$_0$ blocking antibodies.

Rh conglutination test Another test for Rh antibodies of the univalent variety, also known as the direct test for univalent Rh antibodies. When applied to the patient's serum, the initial stage of the test is the same as that for the agglutination or blocking tests. After the red cells have sedimented, however, the supernatant fluid is removed as **completely as possible** and replaced by a drop of albumin-plasma mixture (3 or 4 parts pooled plasma and 1 part 30% bovine albumin). The cells are resuspended and the reactions read after another period of incubation. The technic can be carried out in a tube in a single step by using test cells suspended in 20% albumin solution. The conglutination test, when properly performed, is 5-40 times as sensitive as the blocking test for detecting univalent antibodies. Other modifications of the test have also been devised. See Fig. 485.

antiglobulin test, "developing" test, indirect Coombs test for Rh antibodies Another method for testing for univalent Rh antibodies. The test depends on the fact that the univalent antibodies coating the red cells are human serum globulin. A precipitating rabbit antiserum, prepared by injecting human serum or purified human serum globulin into rabbits (Coombs serum, commercially available), is first absorbed with pooled washed human red cells to remove heteroagglutinins and is then diluted to optimum strength. The patient's undiluted or diluted serum is allowed to react with a saline suspension of Rh-positive cells (group O). The sensitized cells are then washed 3 times

with a large volume of saline to remove the supernatant human serum proteins as completely as possible. A drop of Coombs serum is then added and the mixture centrifuged at 500 r.p.m. for 2 min. If the cells are then clumped, this indicates that they have been sensitized by univalent antibodies; failure to clump indicates the absence of sensitization. See Fig. 486.

Rh antibody tests with enzyme-treated cells If group O, Rh-positive red cells are washed 3 times to remove enzyme inhibitor and then treated with proteolytic enzymes such as trypsin or ficin, they become agglutinable by antisera containing the corresponding univalent Rh-Hr antibody. This test detects the same antibody as the blocking test, the conglutination test, and the antiglobulin test. The test with enzyme-treated cells equals the other tests in specificity and exceeds them in sensitivity. If the sensitivity of the blocking test can be rated as 1, then the sensitivity of the albumin-plasma conglutination test could be rated as approximately 30, the sensitivity of the antiglobulin test as approximately 50, whereas the sensitivity of tests made with enzyme-treated cells could be rated as approximately 100. The reactions obtainable in the tests with enzyme-treated cells are indicated diagrammatically in Fig. 487.

titration Determining the antibody concentration in an antiserum. Unlike chemical titrations, serologic titrations have a large intrinsic error, so that variations up to 100% or 200% are not unusual even in the hands of experts. In the usual technics the test cells are mixed with progressively doubled dilutions of the serum being examined in a series of tubes and the highest

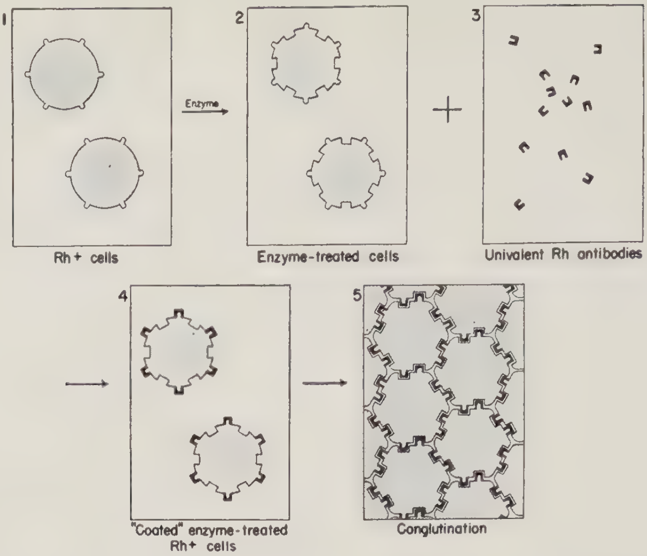

Fig. 487. Clumping of enzyme-treated Rh-positive cells by univalent Rh antibodies. (From Wiener, A. S.: Lab. Digest **14:** No. 6, 1950.)

dilution giving a distinct positive reaction determined.

titer of a serum The amount of specific antibody in an antiserum; the strength of a serum. This is usually expressed in units, which are best calculated by taking the reciprocal of the highest dilution giving a so-called 1-plus reaction. When determining the titer of a testing serum, the method of titration used should correspond to the method used in the actual tests, if the titer found is to have any practical value. The literature contains many reports of fantastically high titers, running into the millions, due in part to "carrying over" and in part to selecting vague reactions as the end point. To avoid such blunders, and in view of the intrinsic inaccuracy of the method, one should calculate the titer values by taking the average of many tests done on different days with many different test cells.

Rh$_0$ blocking serum An **Rh$_0$** antiserum containing univalent **Rh$_0$** antibodies of sufficiently high titer to give a distinct blocking reaction. Depending on the method used, an **Rh$_0$** antiserum must contain a minimum of 5-40 units of univalent antibody, as determined by the conglutination method, in order to give a distinct blocking reaction.

phenotypes The characteristics of individuals of a species as determined by direct observation, measurement, chemical or serologic testing, etc. Thus the characteristics, blue eyes, tall, short, harelip, hemophilic, group O, knock-knees, Rh$_1$-Rh$_2$, etc., all represent phenotypic characteristics. The phenotype may be partly or wholly genetically determined, or it may be entirely determined by the environmental influences, e.g., the color of the hair is usually genetically determined, but in some individuals it may merely be the result of beauty treatment.

Rh typing Classification of individuals within 1 of the 8 standard Rh types with the aid of anti-**Rh$_0$**, anti-**rh′**, and anti-**rh″** sera. Note the distinction between "Rh typing" and "Rh testing."

genotypes The constitutional make-up of an individual as determined by heredity. The genotype is transmitted through the germ cells by means of their chromosomes, although there is evidence also, in rare exceptional cases, of cytoplasmic inheritance. According to the gene theory each of the 23 pairs of chromosomes contains numerous genes arranged in linear order. Every individual has a pair of each kind of genes, one derived from the maternal parent and the other from the paternal parent. The make-up of the individual in terms of these genes is known as his "genotype."

Rh$_0$ phenotypes The 2 phenotypes, Rh positive and Rh negative, can be distinguished by using anti-**Rh$_0$** serum.

Rh$_0$ genotypes The 3 genotypes *RhRh*, *Rhrh*, and *rhrh* are based on Landsteiner and Wiener's theory that the **Rh$_0$** factor is inherited as a simple mendelian dominant by means of a pair of allelic genes, *Rh* and *rh*. Thus Rh-negative individuals are always homozygous *(rhrh)*. When 2 Rh-negative individuals marry, they produce only Rh-negative children. Rh-positive individuals may be either homozygous *(RhRh)* or heterozygous *(Rhrh)*.

homozygous Genetically pure, with genotype consisting of 2 identical genes. If an Rh-negative expectant mother is mated to a homozygous Rh-positive man, all the children will be Rh positive.

heterozygous Genetically impure, with genotype consisting of 2 different genes. If an Rh-negative expectant mother is mated to a heterozygous Rh-positive man, there is 50% chance that the children will be Rh positive and 50% chance that they will be Rh negative, or, as usually stated, 50% of the children will be Rh positive and 50% will be Rh negative.

Rh genes The series of allelic genes that determine the various sorts of Rh agglutinogens and Rh blood types (Table 313). Ten distinct varieties have been completely identified, namely, *r*, *r′*,

r'^w, r'', r^y, R^o, R^1, R^{1w}, R^2, and R^z. These genes each determine corresponding agglutinogens designated as rh, rh′, rh'^{w}, rh″, rh_y, Rh_o, Rh_1, Rh_1^w, Rh_2, and Rh_z. Note that in order to avoid ambiguity between symbols for genes and agglutinogens, italics are used and the letter "h" is dropped when designating genes. Also, while superscripts and subscripts are both used in the symbols for agglutinogens, only superscripts are used in the symbols for the genes in order to conform with the accepted practice of geneticists. Also note that, in addition to the shorthand symbols Rh_1 and Rh_2 (short for Rh_o' and Rh_o'', respectively), the symbol rh_y is used as an abbreviation for rh′″, while Rh_z is short for Rh_o'''. The most common of the 10 Rh genes among Caucasoids are *r*, R^1, and R^2, while R^o, r', and r'' are relatively rare, and r^y and R^z are extremely rare, so that the last 2 can usually be disregarded. On the other hand, R^o is the most common gene in Negroids, while R^z has its maximum frequency of about 3-5% among Mongoloids. *When discussing only the results of tests with* $\textbf{Rh}_\text{o}$ *serum,* which divides people into 2 types, Rh positive and Rh negative, only 1 pair of genes need be considered, namely, *Rh* and *rh*. Obviously, gene *Rh* comprises 5 genes, R^o, R^1, R^{1w}, R^2, and R^z while gene *rh* comprises 5 genes, *r*, r', r'^w, r'', and r^y (Wiener).

Some additional rare allelic genes Wiener has postulated the existence of additional rare alleles—r^v, r^G, R^{ov}, R^{oa}, R^{ob}, R^{oc}, R^{od}, $\mathfrak{R}^o$, $\bar{R}^o$, R^{1a}, R^{1b}, R^{1c}, R^{1d}, R^{1x}, R^{2x}, R^{2a}, R^{2b}, R^{2c}, R^{2d}, $\bar{\bar{R}}^o$, etc.

allelic genes; allelomorphic genes Alternate genes situated at corresponding loci in a pair of chromosomes. Thus genes that influence specific characters such as the blood group, eye color, etc., are located at a specific locus on a pair of chromosomes. All the alternate genes that can be located at a given locus are known as "allelic." Since the locus for the allelic genes of the A-B-O groups is on a different pair of chromosomes from the allelic genes of the M-N-S-U types, while the allelic genes of the Rh-Hr system are on a third pair of chromosomes, these 3 blood group systems are inherited independently of each other. (The Rh locus is not on the sex chromosomes.) When nonallelic genes for 2 distinct characteristics are on the same pairs of chromosomes, they are said to be **linked;** If they are on different chromosomes, they are said to be **independent.**

subtyping for $\textbf{rh}^\text{w}$ **factor** By using anti-$\textbf{rh}^\text{w}$ serum, a subdivision of the 8 Rh types can be made. Factor $\textbf{rh}^\text{w}$ occurs in approximately 5% of Caucasoids, and always in association with factor **rh**′. Thus type Rh_1 (Rh_o') is subdivided into Rh_1^w and Rh_1 proper, type Rh_z into $\text{Rh}_1^\text{w}\text{Rh}_2$ and Rh_1Rh_2 proper, and 1 or 2 examples of rare type rh'^w have been found. A similar subdivision of type rh_y is theoretically possible. The practical importance of the $\textbf{rh}^\text{w}$ factor is to explain rare puzzling examples of erythroblastosis fetalis when both mother and baby are type Rh_1, where the baby is subtype Rh_1^w and the mother has been sensitized to the $\textbf{rh}^\text{w}$ factor.

anti-Hr sera Antisera specific for the Hr factors. These are much rarer than anti-Rh sera, since the Hr factors are usually less antigenic than the Rh factors. Four anti-Hr sera are available: anti-**hr**′, anti-**hr**″, anti-$\textbf{hr}^\text{S}$, and anti-**hr**. The principal practical value of anti-**hr**′ serum is to subdivide type Rh_1 into the 2 types Rh_1Rh_1 and Rh_1rh, and the main value of anti-**hr**″ serum is to subdivide type Rh_2 into Rh_2Rh_2 and Rh_2rh. This gives a presumptive diagnosis of homozygosity or heterozygosity, and aids in anticipating the possible occurrence of erythroblastosis in the unborn child. Anti-**hr**″ sera are rarer than anti-**hr**′. Anti-$\textbf{Hr}_\text{o}$ serum has not been found.

Rh-Hr types, Rh-Hr phenotypes Types of human blood demonstrable by the combined use of Rh and Hr antisera. The number of phenotypes that can be distinguished depends on the number of antisera used in the tests; the evolution of our knowledge as more of the antisera became available is summarized in Table 314. When anti-**hr**′, anti-**hr**″, and anti-**hr** sera as well as anti-$\textbf{Rh}_\text{o}$, anti-**rh**′, and anti-**rh**″ sera are used, 28 Rh-Hr types can be distinguished corresponding to the 55 theoretically possible genotypes. Since $\textbf{Hr}_\text{o}$ antiserum and its presumptive antigen $\textbf{Hr}_\text{o}$ still have not been discovered, the examination will usually be confined to tests for **hr**′ and occasionally for **hr**″, in which case fewer phenotypes can be distinguished. It should be emphasized again that many of the phenotypes are quite rare, especially those involving the agglutinogens rh_y and Rh_z. In selecting the notations for the Rh-Hr types, the principle is employed that the first symbol shall represent the reactions with the Rh antisera, while the second symbol represents the reactions with the reciprocally related Hr antisera. For example, the phenotype Rh_2rh would represent blood reacting with Rh antisera anti-$\textbf{Rh}_\text{o}$ and anti-**rh**″ but not with anti-**rh**′ (Rh_2 = Rh_o + rh″) and with Hr antisera anti-**hr**′ and anti-**hr**″. The phenotype corresponding to any given genotype is determined by adding together the effects of the 2 genes that make up the genotype. For example, if it is desired to know the reactions given by the blood of an individual of genotype R^2r', proceed as in Table 312. The phenotype name for blood giving positive reactions with all 3 standard Rh sera and both standard Hr antisera is $\text{Rh}_\text{z}\text{rh}$, but since anti-$\textbf{Hr}_\text{o}$ serum to date exists only hypothetically,

Table 312. *Reactions of blood of* R^2r' *individuals*

		Reactions with Rh serum			*Reaction with Hr serum*		
		Anti-$\textbf{Rh}_\text{o}$	*Anti*-**rh**′	*Anti*-**rh**″	*Anti*-**hr**′	*Anti*-**hr**″	*Anti*-**hr**
Gene R^2	=	+	−	+	+	−	−
Gene r'.	=	−	+	−	−	+	−
Therefore, by addition, genotype R^2r'	=	+	+	+	+	+	−

the name Rh$_z$Rh$_o$ is used. If tests are made only with the 3 standard Rh antisera, the designation Rh$_z$ must be used.

Rh variants Some blood specimens give weak or intermediate reactions with one or more of the Rh-Hr antisera, demonstrating the existence of variants of the Rh-Hr factors. Of these, the most important are the variants of the **Rh**$_o$ factor, designated $\mathfrak{R}$h$_o$. $\mathfrak{R}$**h**$_o$ factor may occur in the absence of factors **rh**′ and **rh**″ (type $\mathfrak{R}$h$_o$), in association with **rh**′ but not **rh**″ (type $\mathfrak{R}$h$_1$), or in association with factor **rh**″ but not **rh**′ (type $\mathfrak{R}$h$_2$). **Rh**$_o$ variants are rare and occur far more frequently among Negroids than among Caucasoids. In Caucasoids as many as half of the specimens formerly typed as rh′ are now known to belong to type $\mathfrak{R}$h$_1$. The 3 agglutinogens $\mathfrak{R}$h$_o$, $\mathfrak{R}$h$_1$, and $\mathfrak{R}$h$_2$ are inherited by corresponding allelic genes $\mathfrak{R}^o$, $\mathfrak{R}^1$, and $\mathfrak{R}^2$.

Rh-Hr and C-D-E Use of the letters C, D, E for the Rh-Hr types is bound to lead to confusion and errors, since these symbols are based on a disproved genetic theory[62] and the misconception that blood factors and agglutinogens are identical. C = **rh**′; D = **Rh**$_o$; and E = **rh**″. Thus type rh is cde, type rh′ is Cde, type rh″ is cdE, type rh$_y$ is CdE, type Rh$_o$ is cDe, type Rh$_1$ is CDe, type Rh$_2$ is cDE, and type Rh$_z$ is CDE. Much confusion exists in the designation of the genotypes with this nomenclature, and it is suggested that it be dropped from the literature.

HISTORICAL

The Rh antigen was believed at first to be inherited on the basis of a single gene *Rh* and its allele *rh*. As already indicated, Wiener[62] then showed that there were actually at least 6 allelic genes that might possibly occupy a single locus in the chromosome. In 1941 Levine[63] described on the basis of an antibody in blood serum what was essentially just the opposite to Rh and called it Hr. The necessity of including this antigen within the sphere of the Rh antigen led to the possibility of another theory by Fisher and Race.[64] However, this theory had previously been disproved and discarded by Wiener.

In an editorial,[65] J. M. Hill discussed this entire question. He advised that in the light of present knowledge it seems best to abandon all concepts of dominance of Rh genes whether relative or absolute and simply consider all Rh types as determined by allelomorphic genes without dominance. Fisher's synthesis of the results of the British work on the isolation of Rh genes was briefly described by Race in 1944. The Fisher-Race theory proposes that there are 3 possible unlike genes that determine the Hr and Rh phenotypes of an individual. These genes are designated *C-c, D-d, E-e,* and the appropriate combinations of these result in the definite type of individual.

Coombs et al.[66] have discussed Fisher's views completely in an article entitled, "A new test for the detection of weak and incomplete Rh agglutinins." They stated that Fisher, noticing the mutually antithetical reactions of 2 of the 4 distinct types of sera then known (Race, Taylor, Cappell, and McFarlane, 1944) supposed that these 2 sera were reacting with allelic antigens. One of the antigens Fisher called C, and its allele c. The 2 remaining sera did not give antithetical reactions, so the antigens which they recognized were not allelic to each other though they presumably each had an allele. Instead of 7 alleles of the Rh gene at one locus as had previously been proposed, Fisher pictured 3 adjacent loci each with 2 alleles, each allele corresponding to an antigen that was capable of reacting with one antibody only, as shown diagrammatically in Table 315.

The hypothesis required 2 more antibodies, δ and η, unknown at that time. Mourant (1945) has found η. Thus Fisher predicted

*This table does not include hypothetical genes R^{zw} and r^{yw}, which, if they exist at all, are very rare.

†In this table $\mathbf{Rh}_1$ is used as a short designation for $\mathbf{Rh}_o'$, $\mathbf{Rh}_2$ is short for $\mathbf{Rh}_o''$, rh_y is short for rh′″, and $\mathbf{Rh}_z$ is short for $\mathbf{Rh}_o'''$.

‡The reduction in the frequency of type rh′ as compared with that given in earlier charts can be attributed to recognition of bloods of type $\mathfrak{R}\mathrm{h}_1$ (containing Rh_o variant) which are now included in type $\mathbf{Rh}_1$ instead of rh′. The agglutinogens $\mathfrak{R}\mathrm{h}_o$, $\mathfrak{R}\mathrm{h}_1$ and $\mathfrak{R}\mathrm{h}_2$ and their corresponding genes $\mathfrak{R}^o$, $\mathfrak{R}^1$ and $\mathfrak{R}^2$ are not given here because this would serve unnecessarily to complicate the chart by increasing the number of possible genotypes to 91. Also, no attempt is made to include certain rare exceptional bloods, such as those lacking both factors **rh′** and **hr′** or lacking both **rh″** and **hr″**, etc.

§Based on the estimated gene frequencies, $r = 0.38$, $r' = 0.006$, $r'' = 0.005$, $r^y = 0.0001$, $r'^{w} = 0.00005$, $R^o = 0.027$, $R^1 = 0.41$, $R^2 = 0.15$, $R^z = 0.002$, and $R^{1w} = 0.02$.

the existence of 3 antisera reciprocally related to the 3 principal anti-Rh sera. At the time this prediction was made, one of these antisera, anti-**hr′** (or anti-c), was already known. Of the remaining 2, only 1, anti-**hr″** (or anti-e) has been shown with certainty to exist. Instead of anti-$\mathbf{Hr}_0$ (anti-d), a different antiserum, anti-**hr** (or anti-f), has been found, which was not predicted by Fisher.

It may be convenient at this point to summarize the contributions made by British investigators to the field of blood grouping during the past decades. This was initiated in 1942 by Taylor and Race, following publication of the American investigations on the Rh factor. After Taylor's premature death Race took over the leadership of British work and soon confirmed and extended American reports on the serology and heredity of the Rh-Hr blood types. By studying difficult problems of multiple sensitization he and his collaborators discovered the blood factors $\mathbf{rh}^w$, **Levay,** and **Lutheran.** These and other contributions of British investigators are well summarized in the book of Race and Sanger, the third edition of which has been published.[67] Mourant, co-discoverer of the **Lewis** factor, has published an important book[68] summarizing advances in anthropologic aspects of the subject. Mollison, who with Cutbush and Parker discovered the **Duffy** (**F**) factor, studied exchange transfusion and published a fine book on blood transfusion,[69] while Pickles contributed a book on erythroblastosis fetalis.[70] Finally, Dacie has specialized in the study of autosensitization and has published a book on hemolytic anemia.[71] Mention should also be made of the contributions of Coombs and Mourant to the detection of univalent antibodies.[71a]

Table 315

*One must not confuse the agglutinogens with the types. The types (phenotypes) being determined by a pair of genes (genotypes) therefore necessarily comprise a pair of agglutinogens.

†No name given by Fisher or Cappell; anti-f used by Rosenfield et al.

Rh-Hr NOMENCLATURE AND THE C-D-E NOTATIONS

Wiener and Wexler[72] have summarized the fundamental differences between the Rh-Hr nomenclature and the C-D-E notations.

1. Implicit in the C-D-E notations is the concept that each Rh-Hr agglutinogen has but a single blood factor with a single corresponding antibody, making it unnecessary to distinguish between blood factor and agglutinogen. For example, instead of the agglutinogen Rh_1, a set of 4 agglutinogens, *C, D, e, F,* is visualized. As has been pointed out, however, a fundamental principle in immunology is that antigens have multiple corresponding antibodies and thus are characterized by multiple serologic factors. This applies not only to the agglutinogens of the human blood groups but also to the blood groups of cattle, fowl, mice, and even to the antigens of bacteria and viruses, and soluble proteins. The Rh-Hr nomenclature with its distinctive type faces for agglutinogen and blood factors automatically allows for this fundamental serologic reality.

2. The C-D-E-F notations are based on the concept of inheritance of the agglutinogens in uniform sets of 3 (or 4 if postulated F-f pair is included). Actually the number of serologic factors that characterize an agglutinogen is unlimited, because of the complex character of the reacting sites, and thus varies from agglutinogen to agglutinogen, as studies on the Rh-Hr agglutinogens have shown. In this respect the Rh-Hr nomenclature is realistic.

3. The Rh-Hr terminology takes into ac-

count the existence not only of sharply differentiated blood factors but also of graded series of related factors, the latter being indicated by varying the type face, as in the case of $\mathbf{Rh_0}$ variants. The C-D-E notations treat the 2 cases in the same manner. As a result, while the blood factors $\mathbf{C^w}$, $\mathbf{C^x}$ have their corresponding specific antisera anti-$\mathbf{C^w}$, anti-$\mathbf{C^x}$, certain variants of $\mathbf{Rh_0}$ are indicated by the analogous symbol D^u even though there is no corresponding anti-D^u serum.

4. A logical sequel of the concept of a one-to-one correspondence between antigen and antibody is the interpretation of certain sera as containing "linked" antibodies. For example, in the case of the A-B-O system, the anti-**C** antibody had to be designated anti-$A + B$ even though the more reasonable interpretation of the reaction of such antiserum is that it identifies an additional serologic factor of red cells, namely, blood factor **C**. Similarly, in the Rh-Hr system linked antibodies anti-$C + C^w$ had to be postulated to explain the reactions of anti-**rh′** serum with bloods Rh_1^w (CD^weF) as well as Rh_1 (DCeF).

5. The C-D-E notations pretend to indicate in the symbols all of the reactions of the red cell and are therefore presumed to be self-explanatory. The Rh-Hr nomenclature makes no attempt to include all the serologic attributes of the agglutinogen in the symbols, which instead are in the nature of simple mnemonics, as has already been explained. Of interest are the contrasting effects on the symbols of the discovery of anti-*f* (anti-**hr**) and anti-*V* (anti-$\mathbf{hr^v}$) sera. Although the Rh-Hr symbol of gene *r* remained essentially unchanged, the corresponding C-D-E symbol *cde* had to be expanded first to *cdef* and then to *cdefV*. Moreover, it has proved impossible to expand the C-D-E notations to keep abreast of the newer discoveries, such as $\mathbf{Rh^A}$, $\mathbf{Rh^B}$, $\mathbf{Rh^C}$, $\mathbf{Rh^D}$, etc. In fact, in some instances in which the discoveries have not followed the theoretical predictions, symbols for certain factors have been included in the notations even though the factors have not yet been proved to exist, as in the case of *d* and *F*.

6. A serious difficulty with the C-D-E-F notations is the lack of agreement in the use of these symbols by different workers. This is particularly true of the symbols for the various phenotypes. For example, the phenotype Rh_1rh has been variously designated as CcDee; CDe/cde; (+++−); (++−+); C+c+D+E−e+; DCe/−ce; DCeF/dcef; C(A+B+), D(A+), E(A-B+), F(A+); etc.

7. Instead of reporting phenotypes, many workers who use the C-D-E symbols report "most likely genotypes." In fact, the phrase "most likely" is frequently omitted and "genotypes" are reported based on serologic tests alone. This procedure introduces significant statistical errors and in a number of instances has resulted in confusion. As has been pointed out, the Rh-Hr nomenclature has distinctive symbols for phenotypes and genotypes, which automatically avoid this pitfall.

The Committee on Medicolegal Problems of the American Medical Association prepared a report[73, 74] on the medicolegal application of blood grouping tests in which one of the most important problems discussed was that of Rh-Hr nomenclature. In the report the recommendation was made that "unless and until some other convention can be agreed upon, the original Rh-Hr notations be retained as the standard and sole nomenclature for the preparation of approved medicolegal reports on Rh types." In view of the facts that are presented here, it would appear that this recommendation should now be extended to include the applications of the Rh-Hr blood types in clinical medicine and anthropology.

As Wiener has shown, the essential difference between the 2 concepts is on a serologic and not a genetic level. Blood grouping is a subspecialty of immunology, and although a knowledge of genetics is helpful, it is only of secondary importance for mastery of the field. The linkage theory completely evades the fundamental immunologic concept of the difference between an agglutinogen and its serologic attributes, the blood factors, and therein lie the pitfalls of the C-D-E notations. The issue is thus not merely a choice between 2 nomenclatures but also the accuracy in reporting scientific observation.

Rh FACTOR

Reports of posttransfusion reactions when bloods of homologous groups have been transfused, where preliminary tests have been made by experienced observers using reliable and potent sera, indicate that these reactions represent intragroup incompatibilities. Cases of this type have been observed with unusual frequency following primary transfusions given to pregnant or postpartum women. These represent an example of isoimmunization.

It was formerly believed that dangerous transfusion reactions could not occur if both donor and recipient belonged to the same

Landsteiner blood group. Between 1921 and 1939, with the increasing use of blood transfusion, authenticated reports of hemolytic transfusion reactions began to appear in the literature. These hemolytic reactions occurred in spite of the fact that all blood grouping tests showed donor and recipient of the same group and apparently compatible. Unger[56] had observed the first cases of intragroup incompatibility. Both patient and donor belonged to group O, but on cross matching some clumping of the cells was observed. When such blood was transfused, the patient developed chills and fever. Unger believed this reaction was hemolytic in nature. He postulated the existence of 2 different antibodies, the anti-**A** and anti-**B**, which he called the "major" agglutinins, and another antibody which he called the "minor" agglutinin. In cross matching he used cells suspended in serum rather than in saline; he therefore inadvertently, even at that early date, was carrying out the conglutination test. Possibly he was detecting the $\mathbf{Rh}_0$ univalent antibody, although he did not identify it.

In most of the subsequently reported cases no explanation of reactions could be found. In a few instances the patient's blood serum was found to contain **irregular isoagglutinins** and **isohemolysins.** The irregular isoantibodies acted not only on the blood of the donor used in the transfusion but on certain other human bloods as well, independently of the blood groups. Among the most carefully studied instances of this sort were those reported by Unger,[56] Zacho,[75] Culbertson and Ratcliffe,[76] Neter,[77] and Levine and Stetson.[78] No attempt, however, was made to correlate these cases, and the subject remained in this stage until Landsteiner and Wiener reported their discovery of the Rh factor and explained its role in reactions in retransfusions.

Schiff had found that injection of sheep blood into rabbits caused formation of anti-**A** agglutinins and hemolysins. When Landsteiner and Wiener in 1937 detected the presence of M-like agglutinogens in the blood of rhesus monkeys, they found that injection of rhesus monkey blood into rabbits stimulated production of anti-**M** agglutinins. They continued their research in the hope that by using animal blood instead of human blood for preparing antisera they might discover new factors in human blood. They did find that some of their antisera against rhesus monkey blood contained an agglutinin reacting also with the blood cells of 85% of the Caucasoid population, quite independently of the 4 blood groups O, A, B, and AB, or **M**, **N**, and **P** factors. They designated the agglutinogen detected by their anti-rhesus serum "Rh" to indicate the manner in which it was discovered,[79] using the first two letters of the word "rhesus." They did not immediately report their findings because they wished to perform other work on their antisera. In 1939 Wiener and Peters found 3 instances of hemolysis following transfusions of blood of the homologous groups, and these were proved to be due to isoimmunization to the rhesus factor. Thus this new blood factor became clinically very important,[80] and the cases were reported. Wiener stated in his Alvarenga Prize Lecture[81] that this was the reason why the Rh factor found by Landsteiner and Wiener in 1937 was first announced in January, 1940.

Briefly, the blood cells of 85% of all Caucasoids are agglutinated by anti-rhesus (anti-$\mathbf{Rh}_0$) sera. Such cells contain the Rh agglutinogen identified by the factor now designated as $\mathbf{Rh}_0$. These individuals were called Rh positive, whereas the remaining 15%, whose cells lacked the factor, were called Rh negative. Since these Rh-negative blood cells do not possess the $\mathbf{Rh}_0$ factor they therefore are not agglutinated by anti-$\mathbf{Rh}_0$-containing sera.

Since 1940 other Rh factors have been found, **rh′**, **rh″**, $\mathbf{rh}^w$, the variant $\mathfrak{R}\mathbf{h}_0$, and many others, which are described later. Unfortunately, a so-called "simplified nomenclature" was introduced into the literature, following the Fisher "synthesis," but since the nomenclature is based on an erroneous premise, it should be eliminated from the literature. It is neither simple nor correct, as explained on pp. 1496 and 1497.

In recent years attention has been called to the fact that agglutinogens have certain serologic attributes, which Wiener has called "factors"; they are the characteristics by which the agglutinogens are identified. Thus different antisera will cause clumping of cells containing their specific factors, but this does not indicate that all agglutinogens containing such factors are alike. For example, agglutinogen A has a blood factor **C** that it shares with agglutinogen B and another factor $\mathbf{F}_A$ that it shares with sheep red cells.

Of all the blood systems the Rh-Hr is the most complex and, except for the A-B-O system, the most important. The original rhesus factor found by Landsteiner and Wiener and designated $\mathbf{Rh}_0$ is spelled with

Table 317. *Blood groups in man: role in blood transfusion**

System	*Partial list of blood factors*	*Some identifiable types*	*Isoantibodies*		*Role in causing transfusion hemolysis*
			Natural	*Immune*	
A-B-O	**A**, **B**, **C**, **O**, and variants such as A_1, A_2, $A_{1,2}$ and A_3, etc	6 major groups and subgroups—O, A_1, A_2, B, A_1B, A_2B; also rarer subgroups A_3, A_3B, etc.	Regularly present except during neonatal period	Common	Most important
M-N-S-U	**M**, **N**, **M**^{e}, **S**, **s**, **Hu** (Hunter), **He** (Henshaw), **U**, and variants such as M_2, N_2, etc.	6 major types using more readily available sera and anti-**M**, anti-**N**, and anti-**S**	Rare	Rare	Has caused hemolysis in rare cases
Rh-Hr	**Rh**$_0$, **Rh**^{A}, **Rh**^{B}, **Rh**^{C}, **Rh**^{D}, **rh′**, **rh″**, **rh**^{w}, **hr′**, **hr″**, **hr**, **hr**^{S}, **Hr**, and variants such as $\mathfrak{R}$**h**$_0$	28 major types, but of these only 9 with frequencies greater than 1%	A few questionable cases reported	Common	Most frequent cause of intragroup transfusion hemolysis
P-Tj^a	**P** and variants Tj^a	2 major types	Infrequent	Very rare	No cases reported
K-k	**K** and **k**, **Kp**^{a},**Kp**^{b}	3 types	None reported	Occasional	Rare cause of hemolysis in isosensitized patients
Lutheran	**Lu**^{a}, **Lu**^{b}	3 types	None reported	1 case	Very rare cause of hemolysis in isosensitized patients
Duffy (Fy) F-f	**F** and **f**	2 major types, because anti-**f** serum not available	None reported	Several cases	Rare cause of hemolysis
Lewis (Le)	**Le**^{a} and **Le**^{b}	3 types (?)	Infrequent	None found	Plays no role in transfusion hemolysis; **Le**^{a} factor reciprocally related to secretor trait
Kidd (Jk)	**J** and **j**	2 major types, because anti-**j** serum not available	None reported	Few cases	Rare cause of hemolysis
"Private" blood types†					
Rare blood factors	**Levay**, **Gr** (Graydon), **Mi**^{a} (Miltenberger), Becker, **Be**^{a} (Berrens), **Ca**§ (Cavaliere)	Positively reacting bloods very rare	None reported	Very rare	Very rare cause of hemolysis
Factors with almost universal distribution‡	**Tj**^{a}, **U**, **Vel**, **Ge**	Negatively reacting bloods very rare	None reported	1 case anti-**U**; 8 cases anti-**Tj**^{a}	Very rare cause of transfusion hemolysis

*Modified after Wiener, A. S.: New York J. Med. **54**:3071, 1954.

†In the case of the rare blood factors, other individuals possessing such factors are most easily found by testing relatives of the proband, the person in whose blood the factor was first found. Similarly, individuals lacking factors of almost universal distribution are to be found most readily among relatives of the proband. The hereditary nature of the blood factors, in general, is most noticeable in the case of very rare blood types, and Levine has therefore designated them as "private" blood types to indicate their restriction to certain rare families.

‡Factor **k** of the K-k blood types could also be included under this classification.

§Ca and Wr^a are the same—Ca is the preferred symbol.

a capital R to show its great antigenicity and clinical importance. When additional Rh factors were discovered and their relationship to **Rh$_o$** established, the small letter r was used since these were not as antigenic as the originally found rhesus factor **Rh$_o$**. The 2 principal factors aside from **Rh$_o$** are **rh′** and **rh″**. These 3 factors determine the 8 principal Rh types since they may occur alone or in combination.

Eight principal Rh types

When these 3 factors occur alone, they determine 3 Rh types as follows: Rh$_o$, rh′, and rh″.

In combination, the following types may be present in blood:

Rh$_1$, originally called Rh$_o$′, contains **Rh$_o$** and **rh′**.

Rh$_2$, originally called Rh$_o$″, contains **Rh$_o$** and **rh″**.

Rh$_z$, originally called Rh$_o$′″, or Rh$_1$Rh$_2$, contains all 3 factors, **Rh$_o$**, **rh′**, and **rh″**.

rh$_y$, originally called rh′rh″, contains **rh′** and **rh″**.

rh, also called triple Rh negative, contains none of the 3 principal factors.

Table 318. *"Standard" Rh types and percentages*

Rh type	*% in each "standard" type*	*Rh type*	*% in each "standard" type*
rh	14.4	Rh$_o$	2.1
rh′	0.46	Rh$_1$	50.7
rh$'^{W}$	0.004	Rh$_1^{W}$	3.3
rh″	0.38	Rh$_2$	14.6
rh$_y$	0.014	Rh$_z$	13.4
rh$_y^{W}$	0.000051	Rh$_z^{W}$	0.6

*From Wiener, A. S.: J. Forensic Med. 7:93, 1960.

The blood factors are arranged chronologically in the order of their discovery.

The numbers are not intended as a basis for a new nomenclature but may be used as a key if desired.

Variants of Rh$_o$ factor

(1) **Variant $\mathfrak{R}$h$_o$:** In addition to the principal Rh types, a variant of the **Rh$_o$** factor, called **$\mathfrak{R}$h$_o$**, was found by Wiener in 1944.[83] He showed that certain blood specimens gave weak but distinct reactions with certain Rh antisera and appeared to occupy a position intermediate between negatively reacting bloods and those that gave sharp positive reactions. Family studies showed this characteristic to be hereditary. These types are at times designated as **intermediate,** and the genes that determine them are called **intermediate genes.** Although there are other Rh variants, the variant of **Rh$_o$** seems to be the most important because of its antigenicity. The **$\mathfrak{R}$h$_o$** factor, alone or in combination with the 2 Rh factors **rh′** and **rh″**, determines 4 other Rh types as follows:

$\mathfrak{R}$h$_o$, with only **$\mathfrak{R}$h$_o$**
$\mathfrak{R}$h$_1$, with **$\mathfrak{R}$h$_o$** and **rh′**
$\mathfrak{R}$h$_2$, with **$\mathfrak{R}$h$_o$** and **rh″**
$\mathfrak{R}$h$_z$, with **$\mathfrak{R}$h$_o$**, **rh′**, and **rh″**

Unger and Wiener have described variants of **Rh^{A}**, **Rh^{B}**, **Rh^{C}**, and **Rh^{D}** (p. 1502). To distinguish these, the Greek alphabet is used; for example, **Rh$^{\alpha}$**, **Rh$^{\beta}$**, **Rh$^{\delta}$**, **Rh$^{\gamma}$**. Approximately 50% of $\mathfrak{R}$h$_o$ bloods lack one or more of the associated factors **Rh^{A}**, **Rh^{B}**, **Rh^{C}**, and **Rh^{D}**. A superscript small letter is used to designate this, for example, $\mathfrak{R}$h$_1^{a}$rh, $\mathfrak{R}$h$_1^{ad}$rh, etc.

Factor **$\mathfrak{R}$h$_o$** comprises a group giving reactions of intermediate intensity with anti-**Rh$_o$** sera. Blood specimens that react typically with most anti-**Rh$_o$** sera but give slightly weaker reactions with a number of sera are known as high-grade variants, whereas those that react consistently weakly with all anti-**Rh$_o$** sera are low-grade variants. The reactions are determined by the following characteristics: in saline media they fail to react with anti-**Rh$_o$** sera, even those that contain potent anti-**Rh$_o$** agglutinins. They frequently but not always react with univalent **Rh$_o$** antisera by the conglutination method. They almost always react with such sera by the antiglobulin technics, although the avidity and titer of the reactions are generally lower than those for typical **Rh$_o$**-positive bloods. Wiener[84] has pointed out that the bloods of chimpanzees give reactions resembling those of high-grade Rh$_o$ variants.

Table 320. *Reactions of blood with Rh antisera*

*Anti-***rh′**	*Anti-***rh″**	*Anti-*$\mathbf{Rh}_0$	*Phenotype*	*Principal Rh factors present*
Blood lacking $\mathbf{Rh}_0$				
–	–	–	rh, or triple Rh negative	None
+	–	–	rh′	**rh′**
–	+	–	rh″	**rh″**
+	+	–	rh$_y$	**rh′, rh″**
Blood containing $\mathbf{Rh}_0$				
–	–	+	Rh$_0$	$\mathbf{Rh}_0$
+	–	+	Rh$_1$	$\mathbf{Rh}_0$**, rh′**
–	+	+	Rh$_2$	$\mathbf{Rh}_0$**, rh″**
+	+	+	Rh$_z$	$\mathbf{Rh}_0$**, rh′, rh″**

$\mathfrak{R}h_0$ is relatively rare among Caucasoids; it is more frequently found among Negroids.

The important fact to remember is that if this Rh$_0$ variant remains undetermined by laboratory tests, an individual of type $\mathfrak{R}h_1$ will be erroneously typed as rh′, whereas an $\mathfrak{R}h_2$ person will be mistakenly identified as rh″. Those belonging to $\mathfrak{R}h_z$ could be mistakenly identified as rh$_y$. If blood of such individuals is transfused into patients lacking $\mathfrak{R}h_0$, the patient might develop anti-$\mathbf{Rh}_0$ agglutinins and be sensitized. Unfortunately these anti-$\mathbf{Rh}_0$ agglutinins react not only with $\mathfrak{R}h_0$ but with any blood containing the $\mathbf{Rh}_0$ factor as well.

(2) **Type** $\bar{\bar{\mathbf{R}}}\mathbf{h}_0$**:** In 1951, Race et al.[85] found in the serum of a mother of an erythroblastotic baby an antibody that clumped 1400 consecutive blood specimens but failed to clump the mother's own cells. Her red cells reacted with anti-$\mathbf{Rh}_0$ serum but appeared to lack contrasting factors of the 2 pairs **rh′-hr′** and **rh″-hr″** (see under genotypes of the Rh-Hr system), and that is why a double bar is placed above the R in the symbol for this type. These investigators postulated that a deletion had occurred in the Rh "chromosomes" and asserted that the genotype of the mother was -D-/-D-. Wiener disagreed with this interpretation and presented his views based on serologic and genetic principles.

The red cells of this patient were agglutinated in saline media with anti-$\mathbf{Rh}_0$ blocking serum which failed to clump ordinary $\mathbf{Rh}_0$-positive cells under identical conditions. This individual therefore had an agglutinogen similar to agglutinogen Rh$_0$ but differing in its higher reactivity with anti-$\mathbf{Rh}_0$ serum. This property is the fundamental characteristic of the agglutinogen and is due to a modification in its chemical structure. This modification results in increased reactivity with anti-$\mathbf{Rh}_0$ sera and simultaneously crowds out the site of reactivity with all other anti-Rh and anti-Hr sera. For this new type of antigen, Wiener proposed the term **super** $\mathbf{Rh}_0$ and originally assigned the symbol "bar" Rh$_0$, written $\bar{\mathrm{R}}\mathrm{h}_0$. To avoid confusion with another, related type (see below), this symbol has now been changed to double bar Rh$_0$, written $\bar{\bar{\mathbf{R}}}\mathbf{h}_0$.

In an unpublished personal communication (1962) Dr. Unger described a type $\bar{\bar{\mathrm{R}}}\mathrm{h}_0$ blood found in his laboratory after deliberately searching for such a type for approximately 10 yr. He has tested many thousands of bloods during that period, and this is the first one that he has found, pointing to the fact that such blood is very rare. This is a Puerto Rican woman, 82 yr. of age, who required a hysterectomy. She was anemic and a blood transfusion was ordered. All bloods tested were incompatible. The patient's blood was then referred to Dr. Unger. Examination showed the blood to be group O, type MN, type $\bar{\bar{\mathrm{R}}}\mathrm{h}_0$. Unger routinely tests the serum of every donor and every patient for atypical antibodies, using the sensitization test. He found that the serum of this patient contained an antibody. The titer was high and the antibody clumped the cells of all donors' bloods but not her own cells. On further investigation the antibody was classified as anti-**Hr.** (Anti-**Hr** is produced by sensitized persons homozygous for the so-called double bar genes, $\bar{\bar{\mathrm{R}}}\mathrm{h}_0$, $\bar{\bar{\mathrm{R}}}\mathrm{h}^{\mathrm{w}}$, etc.) The bloods of members of her family are being examined, but this has not been completed. The bloods of her children are available, but obviously they are heterozygous for this rare gene and add nothing of interest. Her siblings are in Puerto Rico. At the present writing Unger is making arrangements to obtain the bloods of her siblings in order to complete this study.

Since this variant crowds out the site of reactivity with all other Rh-Hr antisera, the existence of the factor with its gene can give rise to contradictions to the rule that an **rh′**-negative person cannot be the parent of an

hr′-negative child and that an **rh″**-negative person cannot be the parent of an **hr″**-negative child. This subject is considered in medicolegal applications and will be discussed later.

(3) **Type $\bar{\text{R}}\text{h}_0$:** The single bar Rh_0 refers to those individuals whose Rh_0 agglutinogen is characterized by absence of the single pair of contrasting blood factors **rh″** and **hr″**. This type was first described by Wiener and associates.

Other Rh_0 factors

(4) **Type $\bar{\bar{\text{R}}}\text{h}^{w\prime}$:** Refer to $\bar{\bar{\text{R}}}\text{h}_0$ and rh^{w}.

(5) **Rh**$^{\text{A}}$, **Rh**$^{\text{B}}$, **Rh**$^{\text{C}}$, **Rh**$^{\text{D}}$ antibodies related to anti-**Rh**$_0$ have been found by Wiener, Unger, and their associates, in the plasma of persons who have what appear to be typical Rh agglutinogens or variants of the **Rh**$_0$ factor (types Rh_0, Rh_1, Rh_2, and Rh_z and their variants). These individuals usually attract attention because of a hemolytic transfusion reaction or by giving birth to an erythroblastotic baby, after which an antibody is detected in this Rh-positive patient's serum. The antibody seems at first to be identical in specificity to anti-**Rh**$_0$ but differs from typical anti-**Rh**$_0$ in that it does not react with the patient's own Rh-positive blood cells or with those of certain other **Rh**$_0$-positive persons.

Four such antibodies have already been discovered: These are called anti-**Rh**$^{\text{A}}$, anti-**Rh**$^{\text{B}}$, anti-**Rh**$^{\text{C}}$, and anti-**Rh**$^{\text{D}}$.[86-91] The 4 blood factors that they detect may occur in an Rh agglutinogen in any of 16 theoretically possible combinations. **Standard** Rh-positive blood has all these factors, **Rh**$^{\text{A}}$, **Rh**$^{\text{B}}$, **Rh**$^{\text{C}}$, and **Rh**$^{\text{D}}$, as well as **Rh**$_0$. Red cells giving any of the **other theoretically possible reactions** are found in only about 1.6% of Rh-positive Negroes and in only about 0.5% of Rh-positive Caucasians.

Wiener and Unger[92] have explained the foregoing by using the outline of the human hand as a diagrammatic device for representing the Rh_0 portion of the Rh agglutinogens. The webs at the bases of the 4 interspaces between the fingers may be considered to be combining sites for the attachment of antibodies. The web between the thumb and index finger may be considered the site of the combining group for anti-**Rh**$_0$, that between the fourth and fifth fingers for anti-**Rh**$^{\text{A}}$, the web between the third and index fingers for anti-**Rh**$^{\text{C}}$, etc. All so-called "standard" Rh agglutinogens must have the combining site for anti-**Rh**$_0$, but agglutinogens might lack the combining sites for one or more of the antibodies anti-**Rh**$^{\text{A}}$, anti-**Rh**$^{\text{B}}$, anti-**Rh**$^{\text{C}}$, anti-**Rh**$^{\text{D}}$, etc. Since almost all Rh-positive bloods have all associated blood factors **Rh**$^{\text{A}}$, **Rh**$^{\text{B}}$, **Rh**$^{\text{C}}$, **Rh**$^{\text{D}}$, etc., as well as **Rh**$_0$, special complex symbols are assigned **only for the exceptional bloods that lack one or more of the primary blood factors.**

Individuals who lack one of these factors, for example, **Rh**$^{\text{A}}$ (agglutinogen Rh^{a}), but who have factor **Rh**$_0$, can be isosensitized to blood containing **Rh**$^{\text{A}}$. Because such an individual is **Rh**$_0$-positive, the blood cells are agglutinable by standard anti-**Rh**$_0$ serum; but the serum of this individual, even though it appears to contain anti-**Rh**$_0$, will not agglutinate the individual's own cells, which do contain **Rh**$_0$. When such a reaction occurs, investigations must be made to determine whether the patient lacks **Rh**$^{\text{A}}$, **Rh**$^{\text{B}}$, etc.

Rh-positive bloods that lack **Rh**$^{\text{A}}$ are designated as having factor **Rh**$^{\text{a}}$.

Bloods that lack **Rh**$^{\text{B}}$ have factor **Rh**$^{\text{b}}$, and so on.

Unger and Wiener[89] have found Rh_0 variants as well as standard Rh-positive bloods that lack one of the factors **Rh**$^{\text{A}}$, **Rh**$^{\text{B}}$, etc., with a higher incidence among Negroes for those lacking **Rh**$^{\text{A}}$. In most cases Rh_0 variants were associated with a variant of factor **Rh**$^{\text{A}}$ (called **Rh**$^{\alpha}$), or **Rh**$^{\text{B}}$ (called **Rh**$^{\beta}$), or **Rh**$^{\text{C}}$ (called **Rh**$^{\delta}$), and **Rh**$^{\text{D}}$ (called **Rh**$^{\gamma}$), or one or more of these factors were not demonstrable. In no instance has the **Rh**$^{\alpha}$ or **Rh**$^{\beta}$ or **Rh**$^{\delta}$ or **Rh**$^{\gamma}$ factor been found associated with a "standard" **Rh**$_0$ blood factor. Such factors react weakly or not at all with the ficinated cell technic and at times are identifiable only by the ficinated cell-antiglobulin technic.

A summary of the nomenclature regarding one of these factors follows:

Rh^{A}—all Rh agglutinogens having a "standard" **Rh**$_0$ factor and also factor **Rh**$^{\text{A}}$.

Rh^{a}—all Rh agglutinogens having a "standard" **Rh**$_0$ factor but lacking **Rh**$^{\text{A}}$.

$\mathfrak{Rh}^{\text{A}}$—all Rh agglutinogens having a variant of factor **Rh**$_0$ (generally high-grade $\mathfrak{Rh}_0$) and apparently a "standard" or possibly a high-grade variant blood factor **Rh**$^{\text{A}}$.

$\mathfrak{Rh}^{\alpha}$—all Rh agglutinogens having a variant of both blood factors **Rh**$_0$ and **Rh**$^{\text{A}}$.

$\mathfrak{Rh}^{\text{a}}$—all Rh agglutinogens having a variant of blood factor **Rh**$_0$, generally low-grade $\mathfrak{Rh}_0$, but lacking blood factor **Rh**$^{\text{A}}$.

A similar schema may be used for the other Rh factors in this category.

Unfortunately, these multiple blood factors of a single agglutinogen are antigenic, and each is capable of stimulating a corresponding specific antibody in an individual who lacks the factor. Most univalent anti-**Rh**$_0$ sera contain a mixture of Rh antibodies; therefore the rare blood cells lacking one or more of these blood factors are indistinguishable from one another unless the rare antisera specific for such blood factors are available. Similarly, anti-**Rh**$^{\text{A}}$, anti-**Rh**$^{\text{B}}$, etc. cannot be distinguished from anti-**Rh**$_0$ unless one has available, for testing, such rare cells as lack the blood factor for which the antisera are specific. In ordinary cases it is not necessary to test each Rh-positive blood to find the rare individual who lacks one or more of these blood factors, but it is important to be aware that such individuals do exist and that they could become isosensitized through transfusion or pregnancy. Lack of one or more of these blood factors occurs more frequently in Negroids than in Caucasoids and is more likely to be associated with blood containing a variant of the factor **Rh**$_0$. When Negroes receive repeated transfusions, particularly with intervals between transfusions, one must bear in mind that Caucasoid **Rh**$_0$-positive blood is almost invariably positive for all these factors, which may result in sensitization in a Negro who lacks any of the factors. In such cases either Rh-negative blood must be used or blood lacking the specific factor must be found, and there is a better chance of finding such a blood donor among Negroes than among those of other racial groups.

Factors related to rh′

(1) **rh**$^{\text{w}}$: As Wiener has pointed out, variants of each of the 3 so-called standard Rh factors have been found. In addition, each of the factors has related or associated factors. Thus **rh**$^{\text{w}}$ is one of the factors associated with **rh′**. This factor is important in that it can give rise to isosensitization in individuals who lack it.

In 1946 Callender and Race[93] detected in the blood serum of a woman with disseminated lupus erythematosus an antibody apparently formed by immunization from numerous transfusions. Her phenotype was Rh_1Rh_1 (Table 314). She had developed antibodies against factor **hr′** (a blood factor reciprocally related to **rh′**), to **N**, and to 3 previously undescribed blood factors, of which **rh**$^{\text{w}}$ was one. The superscript w was selected to designate the factor detected by her antibody because her name was Willis. It has been found that all persons who have factor **rh**$^{\text{w}}$ also possess factor **rh′**, but blood with factor **rh**$^{\text{w}}$ reacts more weakly with anti-**rh′** serum than does blood that lacks the factor. The incidence of factor **rh**$^{\text{w}}$ is about 3-7% among Caucasoids, so that it is fairly easy to find donors who lack **rh**$^{\text{w}}$.

With anti-**rh**$^{\text{w}}$ serum along with the other Rh antisera further subdivision of the Rh types has subsequently been made: rh'^{w}, Rh^{w}_1, $\text{Rh}^{\text{w}}_1\text{Rh}_2$ (as a subdivision of Rh_z); later Wiener et al.[94] showed that agglutinogens rh^{w}_y and Rh^{w}_z also exist, but these are extremely rare.

If blood of type Rh_1 has been tested for the **hr′** factor and classified as Rh_1Rh_1 (**hr′** negative) or Rh_1rh (**hr′** positive) (Table 314), tests with anti-**rh**$^{\text{w}}$ serum will further subdivide the 2 types as in Table 321. The incidence of positive reactions is considerably higher among individuals of type Rh_1Rh_1 than among individuals of type Rh_1rh.

Table 321. *Subdivision of types* Rh_1Rh_1 and Rh_1rh

Rh type	*Reaction with anti-*$\textbf{rh}^{\text{w}}$ *serum*	*Rh subtype*
Rh_1Rh_1	+	$\text{Rh}^{\text{w}}_1\text{Rh}_1$
	−	Rh_1Rh_1 (proper)
Rh_1rh	+	$\text{Rh}^{\text{w}}_1\text{rh}$
	−	Rh_1rh (proper)

In summary, it is possible for a type Rh_1 individual to have a hemolytic transfusion reaction even if given type Rh_1 blood, if the donor's cells possess **rh**$^{\text{w}}$ and the patient's cells lack this factor. Furthermore, a mother of type Rh_1 may become sensitized to blood factor **rh**$^{\text{w}}$ if present in her fetus' blood (type Rh^{w}_1 or $\text{Rh}^{\text{w}}_1\text{Rh}_2$), and the resulting antibody may give rise to erythroblastosis fetalis.

(2) **rh**$^{\text{x}}$: This is another rare blood factor which occurs only in association with **rh′**.[95] The antibody has been designated anti-**rh**$^{\text{x}}$ and the antigen it identifies, **rh**$^{\text{x}}$. With anti-**rh**$^{\text{w}}$, this antibody shows 3 sharply defined types of the Rh_1 agglutinogens: Rh^{w}_1, Rh^{x}_1, and Rh_1 proper. The last is by far the most common type.

(3) **rh**$^{\text{G}}$: There seems to be a factor shared by both **rh′** and **Rh**$_0$ in much the same manner that factor **C** of the A-B-O blood groups is shared by agglutinogens A and B (refer to p. 1472). Some **Rh**$_0$-negative individuals, sensitized with type Rh_0 blood (which lacks the **rh′** factor), have the capacity of producing

antibodies that react with type rh′ blood (which lacks the **Rh**$_0$ factor). This event has occurred following transfusions. One such serum obtained from an immunized donor[96] reacted with almost equal titer on type Rh$_0$ and rh′ blood and could be completely absorbed with either. It has been designated anti-**rh**^{G}, and the factor it identifies is called **rh**^{G}.

Factors related to rh″

(1) **rh**^{w2}: An antibody described by Greenwalt et al.[97] was found as the cause of hemolytic disease (erythroblastosis). The antigen that it identifies is called **rh**^{w2}. The cells containing this factor are agglutinated by serum containing anti-**rh**^{w2} and by some but not all anti-**rh″** sera. Up to 1958 the antigen had been found in only one family.

(2) **rh**^{u}: An antibody, anti-**rh**^{u}, was found by Race and Sanger[98] in the bloods of an Italian family. This antibody determines the antigen **rh″**^{u}, an antigen found in the agglutinogen **rh″**.

Hr FACTORS

In 1941 Levine and Javert[99, 100] reported that they had detected in the serum of an Rh-positive mother of an erythroblastotic infant an antibody that had the property of agglutinating all Rh-negative bloods. Because of the nature of this antibody, being reciprocal to Rh, it was designated "Hr" and the corresponding agglutinin as "anti-Hr." Levine reported that his anti-Hr serum gave about 30% positive reactions and that all Rh-positive bloods not agglutinated by anti-**rh′** reacted with anti-Hr. On this basis he postulated that Hr and Rh were allelic, without further clarifying his hypothesis. He also asserted that Hr incompatibility must be considered as a possibility whenever an Rh-positive mother has an Rh-negative child and that all type Rh$_1$Rh$_2$ individuals are Hr negative.

According to the observations of Wiener and others, these 2 statements have been contradicted by subsequent findings. For instance, in 1943 Race and Taylor[101] also detected in the serum of an Rh-positive mother of an erythroblastotic infant an agglutinin that reacted with all Rh-negative bloods but differed from Levine and Javert's in that it gave 80% positive reactions. As pointed out by Wiener et al.[102] Race and Taylor's serum detected the same blood property as Levine and Javert's serum, the lower percentage of positive reactions obtained by Levine being due to the use of a weaker antiserum which missed bloods heterozygous for the Hr factor.

More detailed study showed that the Hr factor was related to **rh′** in a manner similar to the relationship between M and N, that is, individual bloods are either rh′ positive or Hr positive, or both, and no blood was rh′ negative and Hr negative.[103] Wiener therefore introduced the designation **hr′** for the factor found by Levine and associates.

In 1944 Fisher[104] noted the reciprocal relationship between factors **rh′** and **hr′** and postulated the existence of 2 additional Hr factors, **hr″** and **Hr**$_0$, related reciprocally to factors **rh″** and **Rh**$_0$, respectively. In 1945 Mourant[105] announced his discovery of an antiserum that gave reactions expected of anti-**hr″**, and Wiener and Peters[106] and others found additional antisera of this specificity. Although several investigators have announced finding antisera of specificity anti-**Hr**$_0$, no confirmation of their work has been made to date, and at the present time (1963) no anti-Hr$_0$ serum is available. Anti-**hr′** and anti-**hr″** sera are used routinely in many laboratories.

The Hr factors can be defined, therefore, as factors reciprocally related to the Rh factors. They are present in agglutinogens only when the corresponding Rh factor is absent from the gene.

The **hr′** factor occurs in 80% of the population and the **hr″** in 98%; that is, only 20% lack **hr′** and only 2% lack **hr″**. The Hr factors appear to be much weaker antigens than the **Rh**$_0$ factor, which explains the relative infrequency of transfusion reactions and cases of erythroblastosis fetalis due to the Hr factors; nevertheless, they are important and must not be ignored.

Individuals who are rh′ negative are virtually always hr′ positive, and those who are rh″ negative are virtually always hr″ positive. (Exceptions are the extremely rare bloods of type $\bar{\bar{\text{R}}}\text{h}_0$, $\bar{\bar{\text{R}}}\text{h}^{w}$, and $\bar{\text{R}}\text{h}_0$). If, however, an Rh factor is present, the corresponding Hr factor may or may not be present. By using the 3 principal Rh antisera and the 2 principal Hr antisera, 18 phenotypes in the Rh-Hr system may be identified. Consult Table 322.

Other Hr factors

(1) **hr**^{S}: In 1960 Shapiro[107] announced his discovery of a new blood factor, now designated **hr**^{S}. The discovery of this new factor

was made during investigation of an unusual case of hemolytic disease of the newborn and was given the superscript S from the name of the mother, Shabalala. Anti-**hr**^{S} reacts like anti-**hr**″ except that certain **hr**″-positive bloods give negative reactions with anti-**hr**^{S}. Anti-**hr**^{S} has been found in all sera tested which hitherto were regarded as of anti-**hr**″ specificity. Bloods that react with anti-**hr**″ but not with anti-**hr**^{S} are designated with a caret; e.g., $\hat{R}h_0$ for the phenotype, and $\hat{R}^o$ for the gene. Bloods lacking **hr**^{S} are fairly frequent in the South African Bantu.

Discovery of the **hr**^{S} factor suggests that many human bloods previously designated Rh$_0$ were in reality $\hat{R}h_0$.

One of the most important facts in Shapiro's investigations is that the so-called "standard" anti-**hr**″ serum usually contains 2 specific antibodies, anti-**hr**^{S} and anti-**hr**″. The amount of pure anti-**hr**″ varies in these sera, a few containing potent anti-**hr**″, some having very little anti-**hr**″, and some having no detectable anti-**hr**″ after absorption with Shabalala's cells.

Sensitization of an **hr**″-positive individual with resultant anti-**hr**″-like antibody production is analogous to the anti-**Rh**$_0$-like antibody produced by some Rh$_0$-positive individuals. These antibodies were classified by Wiener and Unger (p. 1502) as anti-**Rh**^{A}, anti-**Rh**^{B}, anti-**Rh**^{C}, and anti-**Rh**^{D}. It is possible that **hr**^{S} might be the first of a series of associated blood factors related to **hr**″ in the same way as **Rh**^{A}, etc. are related to **Rh**$_0$.

Population and family studies show absence of **hr**^{S} only in certain rare rh and Rh$_0$ agglutinogens (see pp. 1597ff for discussion of genotypes):

Type $Rh_2\hat{r}h$ includes genotypes $R^2\hat{R}^o$, $R^2\hat{\mathfrak{R}}^o$, and $R^2\hat{r}$.

$\hat{R}h_0$ includes genotypes $\hat{R}^o\hat{R}^o$, $\hat{R}^o\hat{\mathfrak{R}}^o$, and $\hat{R}^o\hat{r}$.

$\hat{\mathfrak{R}}h_0$ includes genotypes $\hat{\mathfrak{R}}^o\hat{\mathfrak{R}}^o$ and $\hat{\mathfrak{R}}^o\hat{r}$.

$\hat{r}h$ has genotype $\hat{r}\hat{r}$.

It is also possible that other agglutinogens like Rh$_1$, Rh$_1^w$ may rarely lack **hr**^{S}.

By recognizing the distinction between **hr**^{S} and **hr**″, many paradoxical situations hitherto ascribed to illegitimacy or nonmaternity will doubtless be resolved.

If an antiserum containing only anti-**hr**^{S} is used as an anti-**hr**″ reagent, an Rh$_2$rh blood lacking the **hr**^{S} factor (type $Rh_2\hat{r}h$) will be mistakenly identified as type Rh$_2$Rh$_2$. Wiener had previously (1952) cautioned against the use of anti-**hr**″ sera in tests for exclusion of parentage, citing an example in which the mother was type Rh$_0$ yet her child appeared to be type Rh$_2$Rh$_2$, which, if taken at face value, would indicate that the child was not that of the mother. With the present knowledge of **hr**^{S} antibody in most anti-**hr**″ sera, it seems reasonably certain that the anomalous results reported by Wiener were

due to the fact that the serum he used contained only anti-**hr**^{S} and no anti-**hr″**.

(2) **hr:** An antiserum found by Rosenfield et al.[108, 109] in 1953 was thought at first to be the expected anti-Hr$_0$, but further studies showed that the antibody reacted with blood cells from all individuals carrying the genes R^0 or r, but did not react with blood from persons lacking these genes. The antibody was originally called anti-**f**, but the Rh-Hr symbol adopted by Wiener is anti-**hr**. The **hr** factor merely defines an additional serologic attribute which is shared by the 2 agglutinogens Rh$_0$ and rh, determined by genes R^0 and r, respectively. Anti-**hr** helps distinguish between individuals of genotypes $r'r''$ and r^yr by serologic means alone. Individuals of genotype $r'r''$ are **hr** negative and those of r^yr are **hr** positive. In individuals of type Rh$_z$Rh$_0$, the antiserum aids in distinguishing between those who do and those who do not carry gene R^z, which is of value in cases of disputed parentage. By combining the use of anti-**hr** serum with the 5 standard Rh-Hr antisera, the number of phenotypes that can be determined is extended to 20 as in Table 323.

OTHER RARE Rh-Hr BLOOD FACTORS

(1) **rh$_i$:** An additional factor has been discovered, which, in Caucasoids, is limited to the agglutinogens Rh$_1$ and rh′, determined by the genes R^1 and r', respectively. Anti-**rh$_i$** simulates anti-**rh′** in specificity because of the low incidence of agglutinogens rh$_y$ and Rh$_z$ with which only anti-**rh′** reacts.

Anti-**hr** and anti-**rh$_i$** are useful in resolving parentage disputes involving type Rh$_z$Rh$_0$ putative parents or children. For example, a type Rh$_z$Rh$_0$ person with a type rh or type Rh$_0$ child (or vice versa) would be excluded if he belonged to the common genotype R^1R^2 (or R^1r'' or R^2r') but not if he belonged to one of the rare genotypes R^zr or R^zR^0 or R^0r^y. Therefore, if the blood of such a person is rh$_i$ positive, he is excluded, whereas if it is rh$_i$ negative, he is not.

From the points of view of serology, genetics, and nomenclature, blood factors **hr** and **rh$_i$** may be considered as additional associated blood factors of previously identified Rh-Hr agglutinogens, as in the case of factors **Rh^A**, **Rh^B**, **Rh^C**, **Rh^D**, etc. At the present stage of knowledge, agglutinogen rh is known to have a total of at least 4 blood factors, **hr′**, **hr″**, **hr**, and **Hr**; whereas agglutinogen Rh$^w_1$ has a total of at least 10 blood factors: **Rh$_0$**, **Rh^A**, **Rh^B**, **Rh^C**, **Rh^D**, **rh′**, **rh$_i$**, **rh^w**, **hr″**, and **Hr**. Anti-**Hr** is presently defined as the antibody produced by sensitized persons homozygous for the so-called double bar genes, that is, persons of types $\bar{\bar{\text{R}}}$h$_0$, $\bar{\bar{\text{R}}}$h^w, etc. Double bar Rh agglutinogens (e.g., type $\bar{\bar{\text{R}}}$h$_0$) are defined as those characterized by absence of the 2 pairs of contrasting blood factors **rh′-hr′**

and **rh″-hr″**. Single bar Rh agglutinogens (e.g., type $\bar{\text{Rh}}_o$) are defined as those that lack only 1 pair of contrasting factors, namely, **rh″-hr″**. Recent work[110, 111] has shown that in chimpanzees the Rh-Hr agglutinogen resembles the single bar human Rh agglutinogen.

(2) **Rare Rh factor V, or hr^V:** In 1954 DeNatale et al.,[112] in studying blood with respect to the Rh-Hr system, showed the existence of a new factor, designated **V**. These authors concluded that the antigen is common in Negroids and rare in Caucasoids. The antigen is inherited as a mendelian dominant and has been found to belong to the Rh-Hr system. When it occurs, it is associated with genes *r* and R^o. It is common in Negroes. Geiger[113] reported a case of a white man who had had 25 transfusions without reported reactions. A sensitivity test of his serum showed the presence of antibodies reacting with factor **V**, with a titer of 16 units. The findings were verified by A. S. Wiener, who found an antibody titer of 12 units by the antiglobulin method and 8 units by the ficinated cell technic.

This antibody was found in the routine sensitivity test using the patient's serum against a cell panel suspension, in this case Hemantigen. When antibodies were found, further tests were made, using this patient's serum against specific antigen cells which are now available commercially.* This patient no doubt had received blood from a V-positive donor, which resulted in his sensitization.

ISOIMMUNIZATION (ISOSENSITIZATION) AND TRANSFUSION REACTIONS

Isoimmunization was first noted by Ehrlich and Morgenroth[114] in 1900. Whereas **heteroimmunization** refers to the production of antibodies of a member of a species against an antigen of a member of a different species, **isoimmunization** or preferably **isosensitization** refers to immunization of a member of a species by an antigen derived from another member of the same species. In other words, production of hemolysin in a rabbit after injection with sheep cells is an example of heteroimmunization.

Isoimmunization was first demonstrated when isohemolysins were produced in goats by injecting them with erythrocytes of other goats. In the Ehrlich and Morgenroth goat blood injections, the isoimmune, not the normal, isoantibodies hemolyzed the cells from the goats that had furnished the original inocula, as well as the cells of some but not of all other goats. The serum of the injected goats did not contain an autolysin, that is, it did not affect or combine with the cells of the animal in which the antibody was formed (the injected goat). The observations of Ehrlich and Morgenroth showed the possibility that a considerable number of different antigens might exist in similar cells of different individuals in a single species and also showed that an animal will not ordinarily produce antibodies to antigens that are present in its own blood. Animals can form antibodies against some of their own proteins or other components of their tissues, for example, the substance of the crystalline lens, casein,[115] and an alcoholic extract of brain,[116] but these materials are blood-foreign and thus satisfy one of the primary prerequisites for antigenicity. Immune isoantibodies have been produced in other animals and in fowls.[117]

It is difficult to perform isoimmunization experimentally in man. Thomsen[118] attempted to immunize men by intramuscular injections of incompatible blood, but no significant rise in isoagglutinative titer was observed. This apparent evidence against the isoantigenicity of the A and B group substances is, however, outweighed by the positive evidences which will be presented in reference to the Rh factor. Thomsen's negative result is probably attributable to the relatively small quantity of blood injected, or, possibly, the route of injection was influential in his negative results. Thalhimer[119] reported a case which is an example of the isoantigenicity of group substance B. Here, a boy received 300 ml. of his father's blood; cross matching showed no incompatibility, but no tests were made to determine the 2 blood groups. Only a mild febrile reaction ensued. Eighteen days later, without further tests, the father again served as donor; an alarming reaction stopped the transfusion after 150 ml. of blood had been introduced. Subsequently the bloods were grouped; the son was found to be group O and the father group B. Although no agglutinative titers were determined, it is probable that the anti-**B** normally present in group O plasma (with anti-**A**) was too weak to be detected by the ordinary test and that the primary transfusion of group B blood served as an immunizing stimulus leading probably to a marked rise in the titer of anti-**B**, which thus intensified the incompatibility. There is further evidence that **A** and **B** are isoantigenic in Jonsson's finding[120] that the maternal isohemagglutinins anti-**A** and anti-**B** are of higher titer when the corresponding antigen, **A** or **B** (not present in the mother's blood), is present in the blood of the fetus than when it is absent (transplacental isoimmunization). (Refer to blood factor **C** of the A-B-O system, p. 1472.)

---

*Certified Blood Donor Service, Jamaica, L. I., N. Y., Knickerbocker in New York, and others.

Wiener[121] recorded 2 cases which illustrate isoimmunization of A_2 individuals to A_1 blood. In one the antigenic stimulus was provided by transfusion of A_1 blood; in the other the source of the antigen was a fetus in utero. Because of the presence of immune anti-$\mathbf{A_1}$ isoagglutinins in these patients' sera, only A_2 donors were used in subsequent transfusions, with satisfactory results. These workers presented evidence which indicated that had A_1 donors been used, hemolytic reactions most likely would have resulted. However, the absence of reports in recent literature indicates that subgroups A_1 and A_2, although important, are not quite as important in transfusion as formerly believed.

Further, Wiener and associates state that in selecting donors for subgroups of A and AB it is probably safe to disregard the subgroups except in the rare cases in which the patient's serum contains an irregular isoagglutinin anti-$\mathbf{A_1}$ or anti-$\mathbf{A_2}$. When the irregular isoagglutinin is present, only donors of the homologous group should be used. In this connection Gradwohl cited a case* of a recipient of the A_2B class who had a severe reaction following transfuion of A_1B blood. Later transfusion with A_2B blood resulted in no reaction. This probably corresponds to the irregular isoagglutination mentioned by Wiener.

Davidsohn[122] maintained that the subgroups A_1, A_2, A_1B, and A_2B are significant in causing some posttransfusion reactions, but direct support of this possible mechanism was lacking until Wiener's[121] report was published. Wiener analyzed a case of isoimmunization of an A_2 recipient by transfusion of A_1 blood. The anti-$\mathbf{A_1}$ behaved like a "cold" agglutinin. In another case anti-$\mathbf{A_1}$ antibody was considered to have developed in an A_2 woman as a result of isoimmunization by an A_1 fetus in utero. The general explanation was first presented by Levine and Stetson[123] as the mechanism of reactions following primary intragroup transfusions given intrapartum or postpartum.

The formation of anti-**O** isoagglutinin in low titer has been observed in a group A_1B patient.[124] This suggests that the production of immune anti-**O** isoantibodies may possibly be a factor to be considered in repeated transfusions of blood from universal donors.

Isosensitization may result not only from repeated blood transfusions but also from intramuscular injections of blood or repeated pregnancies or a combination of these, and such isosensitization may in turn be responsible for posttransfusion hemolytic reactions. As Wiener has shown, the development of isoantibodies generally requires at least 2 exposures to the antigen, with an interval of several months between each exposure. The first exposure primes the individual, and subsequent exposures stimulate the production of antibodies. In some cases a long interval is not always necessary, isosensitization resulting from continuous stimulation over a short period of time, with huge quantities of the antigen being given. Unger[125] cited the case of an Rh-negative male patient who received 5500 ml. of Rh-negative blood, and, then, because the patient was moribund and no more Rh-negative blood was available, he was given 54,500 ml. of Rh-positive blood within a period of 7 days. The transfusions were virtually continuous. Rh sensitization tests were negative until the 108th pint of blood was to have been administered, when it was found that the patient had developed univalent $\mathbf{Rh_0}$ antibodies. This is the first reported case of sensitization due to a massive dose of Rh-positive blood transfused into an Rh-negative patient. Ordinarily, an interval of a few months between exposures is necessary, for example, between 2 pregnancies or 2 transfusions bringing on sensitization.

IMPORTANCE OF Rh FACTORS

Rh factors in transfusions and retransfusions

Rh-negative individuals may become sensitized to Rh antigen in 1 of 2 ways: (1) sensitization may result from a transfusion of Rh-positive blood or (2) in women, sensitization may result from pregnancy with an Rh-positive fetus. Sensitization by either of these methods may result in a serious hemolytic reaction if transfusion with Rh-positive blood is given. Therefore, all Rh-negative women who are to be transfused **must** be given only Rh-negative blood.

---

*Record of the Christian Hospital, St. Louis, Mo.

It had been observed for many years prior to 1940 that incompatible transfusion reactions occurred in a number of cases when the same donor's blood was used to transfuse a patient the second time, even though the first transfusion with such blood gave completely compatible results. These reactions took place even when both the donor and recipient were of the same blood group. After the discovery of the Rh factor by Landsteiner and Wiener, it was demonstrated that these incompatible intragroup reactions which had occurred in repeated transfusions of a patient with the same donor's blood (or blood of a compatible group) were due in most cases to incompatibility of the Rh types. Wiener demonstrated that the Rh factors are antigenic to man and that Rh-negative individuals may become sensitized to the Rh factor as a result of transfusion with Rh-positive blood.

If a patient who lacks the Rh factor is transfused with blood containing the factor, the transfused patient forms anti-Rh agglutinins which persist in his blood, and he thus has become isosensitized to the Rh factor. If he is again transfused with blood containing the Rh factor, the antibodies formed as a result of the first transfusion combine with the incoming Rh-positive donor cells and a transfusion reaction results.

The most antigenic of all the Rh factors is $\mathbf{Rh_o}$, and this factor is found in 85% of all Caucasoids. It is dangerous to give any blood containing $\mathbf{Rh_o}$ to any individual who lacks it because that person becomes sensitized to Rh. The other Rh factors are also antigenic; therefore, Rh-negative individuals must be transfused only with triple Rh-negative blood.

It is also important not to transfuse blood of Rh-sensitized donors into patients, especially into Rh-negative recipients, since introduction of antibodies that later could prove harmful is not good practice. It has been shown that antibody titer is easily enhanced with the introduction of incompatible cells into an individual with low-titer antibodies. This is the so-called **anamnestic reaction.**

In routine procedure the patient is tested for the presence or absence of $\mathbf{Rh_o}$. If this factor is not present in the patient's blood, only Rh-negative donor blood is given. A patient may lack $\mathbf{Rh_o}$ but his erythrocytes may have any of the other Rh factors. Unless a donor of the exact Rh type can be found in such cases, it is safest to transfuse this patient with triple Rh-negative (type rh) blood, that is, blood that lacks the 3 principal Rh factors, $\mathbf{Rh_o}$, **rh′**, and **rh″**.

If a patient of type rh′ is transfused with Rh_o-positive blood, this patient will become isosensitized to the $\mathbf{Rh_o}$ factor, or, in other words, his blood will contain anti-$\mathbf{Rh_o}$, and a second transfusion with Rh_o-positive blood will result in a transfusion reaction. Since it is easier to obtain type rh (triple Rh-negative) blood than either type rh′ or rh″, this patient should be given type rh blood.

If rh′ blood is given in a transfusion to an Rh-negative patient or to a patient of type Rh_2, the patient will form anti-**rh′** antibodies and therefore become isosensitized. It is for such reasons that complete Rh typing tests should be made of all donors' bloods before using them in transfusions.

Rh factors in primary transfusions of pregnant women

For the sake of simplicity of explanation in this discussion, individuals will first be considered as either Rh positive or Rh negative.

In respect to transfusing females from birth to the climacteric, if they are Rh negative and are transfused with Rh-positive blood, they may develop Rh antibodies. These antibodies may persist for life, so that if another transfusion is required and Rh-positive blood is used, severe transfusion reactions may occur as a result of the antibody-antigen reaction. Particularly the fact must be borne in mind that these Rh-negative females, who have been transfused at some time in their early life with Rh-positive blood, are isoimmunized to the Rh factor, so that when undertaking marriage and upon becoming pregnant, if the fetus is Rh positive they will most certainly have intragroup transfusion reactions if transfused with Rh-positive blood. Moreover, their chances of bearing normal infants are endangered if the fetus is Rh positive.

(The rules for the Rh factor as applied to the operation of a blood bank have been described by Unger.[126])

The Rh types of blood are hereditarily determined,[127] the $\mathbf{Rh_o}$ factor being transmitted as a simple mendelian dominant by a pair of allelic genes, *Rh* and *rh* (*Rh* determines Rh positive; *rh* determines Rh negative). Since every individual possesses a pair of genes from every series of allelic genes, one being derived from the mother and the other from the father, there are 3 genotypes possible. Rh-negative individuals belong to genotype *rhrh* and are always homozygous; Rh-positive individuals may be either homozygous (genotype *RhRh*) or heterozygous (genotype *Rhrh*). Therefore, 2 Rh-negative parents can have only Rh-negative children. If one parent is Rh negative and the other is Rh positive, the children will all be Rh positive if the Rh-positive parent is homozygous. If the Rh-positive parent is heterozygous, there is equal chance that the children may be Rh positive or Rh negative; or as it is usually stated, one-half of the children will be Rh positive and one-half will be Rh negative. When both parents are Rh positive, all the children will be Rh positive, except when the parents are both heterozygous, in which case one-fourth of the children will be Rh negative.[128] For a fuller discussion see heredity of the blood groups, pp. 1597ff and 1606-1612.

In 1940 Levine et al.[129, 130] noted that sera of patients who had had repeated miscarriages or abortions contained atypical isoagglutinins related to the Rh factor. In 1941 Katzin found that the serum of the patient previously described by Levine and Stetson[123] agglutinated the same cells as the newly discovered anti-rhesus rabbit serum. Levine et al.[131] called attention to the fact that a diagnosis of erythroblastosis fetalis had been made on some of the dead fetuses which came from the union of Rh-positive and Rh-negative persons. Vogel[132, 133] noted that the majority of the mothers had Rh-negative blood. Burnham[134] and Levine[135, 136] further called attention to the relationship of the Rh factor to erythroblastosis. The doctrine that Rh-positive fetal cells entering the maternal blood stimulate the formation of anti-Rh agglutinins is now accepted. Such agglutinins pass back to the fetus and then clump and destroy the fetal erythrocytes.

An excellent description of what takes place in the placenta itself was given by Pieri and Schwartz[137] (Figs. 488 and 489). The medium for the interchange of gases, water, and nourishment between mother and baby is the fragile membrane of the placental villus, a trophoblastic projection of the chorion frondosum itself. Through an arteriole, each villus is supplied with fetal blood by a branch from one of the umbilical arteries, while a corresponding venule eventually returns the blood to the fetal circulation. The delicate placental villi are bathed in pools of maternal blood in the intervillus spaces. The maternal blood is carried to these spaces by minute branches of the uterine artery, which are usually found in relation to the decidual septa, while corresponding veins return it eventually to branches of the uterine vein. Constant circulation is assisted by the uterine contractions which occur at intervals throughout every pregnancy. Normally, the blood of the child circulates inside the villus, while the maternal blood circulates outside this delicate structure. The relationship is so close that osmosis readily takes place through the villus wall. It has been estimated that if all the villi of a placenta at full term were placed end to end, their combined length would exceed 11 miles.

That the placenta is extremely susceptible to the effects of tumors, trauma, and disease has long been known. This is not a surprising observation in view of the complex structure and function of this organ and the fact that the more complex an organ the more delicate and vulnerable to injury it becomes.[138] Careful scrutiny of the placenta[139] will reveal in nearly every instance the unmistakable evidences of one or many areas of old or recent pathologic alteration. Such scars, varying in size from pinhead to several c.mm., have been designated by a confusion of terms, such as infarction, hepatization, placentitis, necrosis, apoplexy, etc. Actually each such scar represents merely the evidence of a previous placental injury. Since the most delicate portion of the placenta is the villus itself, this structure is the most susceptible to injury as a result of apoplexy, hemorrhagic infarction, or direct trauma. Whatever the causative factor, any violent break in the continuity of the vessels of one or more villi will result in hemorrhage of fetal blood cells into the maternal circulation. From here the fetal blood elements are carried into the uterine veins and thence into the general circulation of the mother. Such a hemorrhage may be minute and apparently insignificant, or it may be of considerable size.[140] (In fact, Wiener has described an anemia of newborn babies due to occult placental bleeding of fetal blood into the maternal circulation.[141]) Either may produce most serious sequelae.

Now, if the fetus' cells contain the Rh antigen (Rh positive) while those of the mother are without the antigen (Rh negative), a variable degree of isoimmunization may result. The Rh-positive cells of the fetus stimulate within the Rh-negative mother formation of the specific Rh antibody (anti-Rh agglutinin).

If the mother now needs a transfusion and Rh-positive donor blood is used, there follow

hemolysis and agglutination of the donor's cells, with resulting renal damage or even death, from the action of the mother's isoantibodies (anti-Rh) on the incoming Rh-positive cells. Therefore, in all primary transfusions of Rh-negative pregnant or postpartum women use Rh-negative donors.

Rh factors in erythroblastosis fetalis*

The Rh antibody formed in the blood serum of the Rh-negative mother by virtue of the presence of an Rh-positive fetus (see previous discussion on Rh factors in primary transfusions of pregnant women) is readily transmissible (when it is univalent) as are many toxins and antitoxins, through the placental filter (the walls of the villi) into the circulation of the infant in utero. It is the action of this antibody upon the Rh-positive cells of the baby that produces a disease entity recognized as isohemolytic disease or erythroblastosis fetalis which in about 90% of the cases is due to incompatibility of the Rh factors. In most of the remaining 10% the disease apparently depends upon similar genetically re-

lated antigens (such as those designated as Hr or other blood group antigens) present in the baby's cells but absent in those of the mother.

Fig. 490 illustrates what takes place in pregnancy when an Rh-negative woman is mated to an Rh-positive man. The Rh positive fetus stimulates formation of Rh antibodies in the mother (isoimmunization). Anti-Rh antibodies from the mother pass through the placenta, producing hemolytic changes in the fetus. This may result in stillbirth or in erythroblastosis fetalis if the infant is born alive. It must be noted, as Wiener first pointed out, that only the univalent antibodies enter the fetal circulation so that if bivalent antibodies alone are formed by the mother, the infant is not affected.

Although the mating of Rh-negative women with Rh-positive men occurs in 1 out of 10 marriages, congenital hemolytic disease affects only 1 in about 250 newborn infants. This suggests that only about 1 in 25 Rh-negative women becomes sensitized when bearing an Rh-positive fetus, just as in sensitization by blood transfusion. The first-born child is rarely affected, because it takes at least one pregnancy and sometimes more before a sufficient degree of sensitization develops. In most of the rare cases in which the first-born infant was affected, a careful history has revealed that the woman had previously received a transfusion of Rh-positive blood. According to Wiener, this serves to emphasize the importance of performing Rh tests before giving blood transfusions to women in the childbearing age, as well as to young girls, because a transfusion of the wrong Rh type blood could ruin a woman's chances of having a normal child. (Refer to pp. 1488 and 1489 and below for a discussion of univalent antibodies.)

If the infant is transfused with Rh-positive cells, the Rh antibodies derived from the mother, which are in excess of those that coat the infant's cells, react with the incoming Rh-positive donor blood cells and a reaction ensues.

Therefore, in all pregnancies in which the mother is Rh negative and the father is Rh positive be prepared for an erythroblastotic infant. If a direct antiglobulin test (Coombs test) of the infant's cells is positive at birth, transfuse the infant immediately upon birth with Rh-negative donor blood, or, preferably, perform an exchange transfusion using Rh-negative blood. If no Rh-negative donor is available, use the washed red cells of the Rh-negative mother. Washing the cells removes the Rh antibodies. In emergencies, however, the mother's whole blood may be used. See pp. 1537ff for exsanguination or exchange transfusions.

NATURE OF ANTIBODIES*

Antibodies appear in the blood in 2 principal forms: (1) **univalent**—also called conglutinating, blocking, incomplete, or coating antibodies—and (2) **bivalent**—also called agglutinating, complete, precipitating antibody. The univalent antibodies occur later in the course of immunization than do the bivalent antibodies, are relatively thermostable, and readily pass through the intact placenta. Many of the univalent antibodies combine with and coat their specific cells when such cells are suspended in a saline medium, but the cells do not clump. When high molecular colloids or proteins are present, the univalent antibodies cause the cells to clump. On the other hand, bivalent antibodies will react with cells that are suspended in saline media as well as with cells suspended in high molecular colloids. Bivalent antibodies are usually produced early in the course of immunization, are relatively thermolabile, and are effectively held back by an intact placenta.

---

*See Table 311.

The use of the terms univalent and bivalent is not intended to imply chemical valence. These terms were coined by A. S. Wiener in order to impart a visual concept of in vitro reactions. See Figs. 484-487 and 494.

It must be assumed that the bivalent molecule, which has a probable molecular weight of 930,000 against a 155,000 molecular weight of the univalent molecule, is larger and therefore cannot transverse the placental barrier. In syphilis the bivalent antibody is a flocculating antibody, whereas the univalent antibody is a complement fixing antibody. The antisheep hemolysin used in complement fixation tests is regarded as a univalent antibody since it requires complement to complete its reaction with sheep cells.

The anti-**A** and anti-**B** agglutinins are in most cases bivalent antibodies, whereas anti-**C** (of the A-B-O system) is more often univalent. Rh antibodies may be univalent or bivalent, or both may be present in the same serum. For this reason tests for both types of antibodies should always be made with unknown serum when sensitivity testing is done.

Univalent antibodies "coat" cells but lack the capacity to clump them in saline medium, and since the antibodies are gamma globulins, this coating can be detected by the antiglobulin method.

Wiener[143] described the difference between the 2 varieties of antibodies and their reaction in vitro as follows:

Anti-Rh agglutinins (bivalent) + Rh-positive cells = Rh agglutination.

Anti-Rh glutinins (univalent or blocking antibodies) + Rh-positive cells + X protein = Rh conglutination.

The third component listed here, X protein, is a normal component of blood serum. It is adsorbed onto the specifically sensitized red cells, causing them to stick together. This X protein is distinct from complement. It resists heating at 60° C. and is a colloidal constituent or conglutinin in the plasma, a large molecular complex of albumin, globulin, fibrinogen, and phospholipid. X protein, although heat-resistant, dissociates readily into its constituent smaller molecules of albumin and globulin upon dilution of the plasma or serum with water. Use of saline to suspend cells or to dilute serum may either partially or completely dissociate the X protein. Thus, in order to carry out conglutination tests, any crystalline solution must be strictly avoided.

Chapter 75

Tests for the determination of the Rh-Hr factors

ADDINE G. ERSKINE

When determining blood groups and types, there must be available a battery of antisera, that is, sera containing specific antibodies. Each antiserum contains only antibodies specific for the blood factor in question and no other antibodies. The blood factors detected by the various antisera are not all independent of one another but fall naturally into sets which are known as blood group systems.

DETECTION OF Rh FACTORS IN BLOOD CELLS

A requisite for accurate and successful Rh testing is an efficient anti-Rh serum. Originally the source of such serum was from women who had given birth to erythroblastotic babies or who had had spontaneous abortions or stillbirths resulting from Rh incompatibility. More recently, a number of reliable biological houses* have produced excellent anti-Rh testing sera by immunizing normal male professional blood donors (p. 1532). The original anti-Rh serum was produced in animals by inoculating them with rhesus monkey blood, but such sera have some disadvantages—the amount of blood obtainable is small, absorption with Rh-negative cells is necessary to remove undesirable antibodies, and anti-Rh sera from animals immunized with rhesus blood contain only the antibody corresponding to anti-**Rh**$_0$.

Two types of anti-Rh sera are available. One, called conglutinating serum, may be used for blood cells suspended in their own serum or plasma or fortified with conglutinin. It is not reactive with saline-suspended cells. Such sera are used in the open slide methods and for detecting **Rh**$_0$ variant, as well as for coating Rh-positive cells. The other type, called agglutinating serum, may be used for cells suspended in saline as well as in conglutinin. Such antisera are used for the tests made in tubes in which saline-suspended cells are used. Either can be used for enzyme-treated cells.

Conglutinating antisera of 3 Rh specificities* are available for Rh testing: (1) anti-**Rh**$_0$ will detect the **Rh**$_0$ factor in types Rh$_0$, Rh$_1$, Rh$_2$, and Rh$_z$; (2) anti-**Rh**$_0$′ will detect both the **Rh**$_0$ and the **rh′** factors found in types Rh$_0$, Rh$_1$, Rh$_2$, Rh$_z$, rh′, and rh$_y$; and (3) anti-**Rh**$_0$″ will detect both the **Rh**$_0$ and the **rh″** factors found in types Rh$_0$, Rh$_1$, Rh$_2$, Rh$_z$, rh″, and rh$_y$. Manifestly, if the unknown blood cells have the **Rh**$_0$ factor, all 3 antisera will cause their agglutination. But if the **Rh**$_0$ factor is not present in the cells while either **rh′** or **rh″** is present, or if both **rh′** and **rh″** are present, then one or the other of antisera (2) or (3) above will cause their agglutination. These so-called "slide" sera are used primarily for screening tests to determine whether or not **Rh**$_0$ is present, or, if it is absent, whether or not **rh′** or **rh″** is present. Actual identification of the 8 primary Rh blood types cannot be made with these conglutinating sera. Tube tests must be made, using agglutinating sera of different specificities, and each factor determined separately.

---

*Certified Blood Donor Service, Inc., Jamaica, L. I., N. Y,; High Titer Serum Laboratories, New York, N. Y.; Ortho Pharmaceutical Co., Raritan, N. J.; Knickerbocker Laboratories, New York, N. Y.; Hyland Laboratories, Los Angeles, Calif.

*This does not include conglutinating sera of anti-**hr′** and other specificities.

Anti-$\mathbf{Rh}_0$ serum shows 85% of all bloods from Caucasians tested to be Rh positive; anti-$\mathbf{Rh}_0'$, when used alone shows slightly less than 87% of all bloods from Caucasians to be Rh positive; whereas anti-Rh_0'', if used alone, will show about 85.5% of all Caucasian bloods to be Rh positive.

Agglutinating sera for Rh typing are of 3 main specificities: anti-$\mathbf{Rh}_0$, which detects the $\mathbf{Rh}_0$ factor (present in 85% of Caucasoids), anti-$\mathbf{rh}'$, which detects the $\mathbf{rh}'$ factor (present in 70% of Caucasoids), and anti-$\mathbf{rh}''$, which detects the $\mathbf{rh}''$ factor (present in 30% of Caucasoids). (In addition to tests with these 3 antisera, a test is also made for the $\mathbf{Rh}_0$ variant, using anti-$\mathbf{Rh}_0$ conglutinating serum plus an antiglobulin test.) If blood is type Rh_1 (Rh_0'), the cells are agglutinated in the tube test by both the anti-$\mathbf{Rh}_0$ and the anti-$\mathbf{rh}'$ sera; if it is Rh_2 (Rh_0''), it is clumped by both anti-$\mathbf{Rh}_0$ and anti-$\mathbf{rh}''$; and if it is Rh_z (Rh_0'''), it is clumped by all 3 of these antisera.

Slide method

When testing the patient, use the anti-$\mathbf{Rh}_0$ serum as a routine procedure. If this recipient is Rh negative by the slide test, give only Rh-negative donor blood in a transfusion. If the blood proves to be Rh-positive, give Rh-positive blood.

When testing donors, all 3 conglutinating antisera should be used routinely as previously explained. If the donor's blood is aglutinated by the anti-$\mathbf{Rh}_0$ serum, all 3 tests will be positive. If the test with anti-$\mathbf{Rh}_0$ is negative but either or both the other 2 tests are positive, this donor is considered Rh positive and the blood is **not** to be used for Rh-negative recipients. If positive by any of the 3 tests, the blood is given only to Rh-positive recipients.

If the results with all 3 antisera are negative, the blood may be used for Rh-negative recipients, provided that tube antiglobulin tests prove the absence of $\mathfrak{R}\mathbf{h}_0$.

Equipment:

1. A special viewing box is used for this test. This box is fitted with an electric light globe which will bring the temperature on the plate to 45°-47° C. See Figs. 476 and 477. Since some time is required to bring the temperature on the glass plate to the proper degree, the light should be on at all times.
2. Ordinary glass microscope slides are used.
3. In addition to the antisera, whole blood taken in a special dry anticoagulant is used (pp. 1461 and 1462). If clotted blood is submitted, break up the clot and suspend the cells to a concentration of 50% in their own serum. Do not use blood taken in a crystalline solution (saline, sodium citrate, liquid oxalate, etc.). The patient's blood should be centrifuged and enough plasma removed to bring the cell concentration to 50%.

Reagents: For recipients, use anti-$\mathbf{Rh}_0$ slide (conglutinating) serum alone; use all 3 antisera, anti-$\mathbf{Rh}_0$, anti-$\mathbf{Rh}_0'$ and anti-$\mathbf{Rh}_0''$ sera for donors. (If blood bank blood is used, the exact type of blood of the donor is often given on the blood bottle. This can be detected by use of the tube-agglutinating method. See below.)

Procedure: Carry out the method for each antiserum used.

1. Make a large oval ring on a glass slide, using a red wax pencil. The oval is about 1½ × ¾ in.
2. Label with the name of the individual being tested and the serum used. See Fig. 482.
3. Place 2 drops of whole blood on the slide.
4. Add 1 large drop of antiserum (anti-$\mathbf{Rh}_0$ if this is the recipient).
5. Prepare similar slides for each antiserum used to test the blood.
6. Mix each with a separate wooden applicator, spreading the mixture over the entire surface of the oval ring.
7. Place on a preheated viewing box and rock back and forth, observing for clumping or lack of clumping.
8. At the end of 3-5 min. tip the box and add a drop of saline to the top of the slide so that it runs down into the mixture. Rouleaux will be broken up by the saline, but true clumping will not.
9. Read macroscopically only; do not read under a microscope.
10. Wait for 1 or 2 min. before taking the final reading.
11. Report clumping as positive, lack of clumping as negative.

Controls: At the same time run parallel tests using known Rh-positive and Rh-negative whole blood as controls. If these react correctly, the results in the tests may be reported. If the controls give incorrect reactions, do not report the results of the tests until new antisera are obtained and the tests and controls have been repeated.

Results possible: For the recipient, see Table 324; for the donor, see Table 325.

Tube method

This test should be made routinely on all Rh-negative donors and preferably also on all Rh-negative patients.

Reagents: Anti-$\mathbf{rh}'$ saline agglutinating serum, anti-$\mathbf{rh}''$ saline agglutinating serum, anti-$\mathbf{Rh}_0$ saline agglutinating serum, anti-$\mathbf{Rh}_0$ conglutinating (slide test) serum. The anti-$\mathbf{Rh}_0$ conglutinating serum is used to detect the Rh_0 variant $\mathfrak{R}\mathbf{h}_0$ or D^u).

In addition to these sera, a 5% suspension of the patient's (or donor's) cells in saline is needed. Make the suspension as directed on p. 1463, wash once in saline, and resuspend to a 5% suspension in saline.

Use tubes 7.5 cm. × 8 mm., 4 for each test. Refer to Figs. 491 and 492.

*Tests should be made for the **Rh**$_0$ variant, $\mathfrak{Rh}_0$.

†Give this blood only to Rh-positive patients. This individual should receive only Rh-negative blood unless the exact type is available. Tests should be made for the $\mathfrak{Rh}_0$ factor.

Procedure:

1. Label tubes with the identification of the individual being tested and the identity of the antiserum.
2. Place 1 drop of cell suspension to be tested in each of 4 tubes in a rack. Use the same dropper held at the same angle so that the drops in each tube will be approximately the same size.
3. Add:
   - 1 drop of anti-**rh**′ saline agglutinating serum to tube 1
   - 1 drop of anti-**rh**″ saline agglutinating serum to tube 2
   - 1 drop of anti-**Rh**$_0$ saline agglutinating serum to tube 3

Fig. 492. Tube test for Rh factors in cell suspensions.

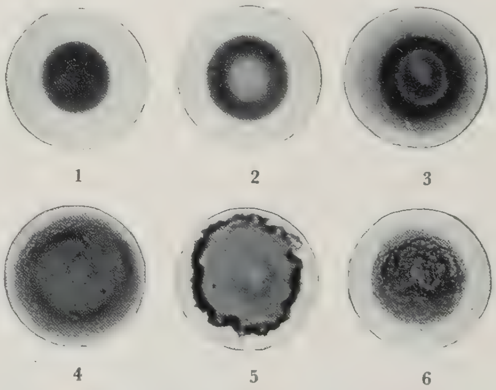

Fig. 493. Magnification 1:2. **1** and **2,** Negative reactions; the inner light disk in **2** is due to slight convexity in the bottom of the tube. **3,** Faintly positive reaction. **4,** Weak reaction. **5** and **6,** Typical positive reactions. (From Landsteiner, K., and Wiener, A. S.: J. Exper. Med. **74:**312, 1941.)

1 drop of anti-**Rh**$_0$ slide agglutinating (conglutinating) serum to tube 4.

4. Mix and incubate in a water bath at 37° C. for 1 hr.
5. Tip the rack and take a preliminary reading from the bottoms of the tubes (Fig. 493). Negative reactions come down in a pear shape, whereas positive reactions tend to remain round.
6. Read over a lighted box, spreading the mixture thin in the tube. Read under a scanning lens of a microscope, reporting clumping as positive and lack of clumping as negative. The reactions are easier to read if the tubes are centrifuged at low speed for 1 min. or if they are left at room temperature for 1 hr. before reading.

If the result in tube 3 (anti-Rh$_0$ saline agglutinating serum) is negative, use tube 4 for an antiglobulin (Coombs) test as follows:

7. Wash the cells in tube 4 three times with saline. After the last washing remove all traces of the saline. This can be accomplished by centrifuging at high speed, turning the tube upside down after the cells have been packed and striking the lip of the tube on a gauze pad while the tube is still upside down.
8. Shake thoroughly and incubate for 5 min. in a water bath at 37° C.
9. Add 1 drop of antiglobulin (Coombs) serum.
10. Mix thoroughly and centrifuge at 500-1000 r.p.m. for 2 min.
11. Read over a lighted box and under a scanning lens. Consult Table 326 for results.

If the results in tube 3 (anti-**Rh**$_0$ saline agglutinating serum) **are positive,** omit the Coombs test on tube 4 because it will always be positive under these circumstances.

If the anti-**rh'** serum clumps the cells, **rh'** factor is present.

If the anti-**rh''** serum clumps the cells, **rh''** factor is present.

If the anti-**Rh**$_0$ saline agglutinating serum clumps the cells, **Rh**$_0$ factor is present.

If the anti-**Rh**$_0$ saline agglutinating serum fails to clump the cells but the Coombs test is positive in tube 4 (slide agglutinating anti-**Rh**$_0$ serum), the **Rh**$_0$ variant is present. This is reported by using the box as given in Table 326, as suggested by Unger.

Rapid tube method

1. Place 1 large drop of conglutinating anti-**Rh**$_0$ testing serum (slide serum) in a small tube, inside diameter 7-8 mm.
2. Dip a wooden applicator into the sample of blood to be tested, either whole oxalated blood or clotted blood, to pick up some of the red cells.
3. With the applicator transfer enough unknown cells to the tube containing the antiserum to prepare a 2% suspension of red cells in the serum.
4. Place the tube in a water bath at 37° C. for a few minutes to warm it and then centrifuge at 500 r.p.m. for 1 min.
5. Shake gently to free the sediment. In positive reactions the sediment comes away in a single clump or several large clumps. In negative reactions the cells separate to form a homogeneous suspension.
6. Check the readings microscopically, using a scanning lens.
7. Instead of centrifuging the tubes, allow them to stand for 1 hr. in a 37° C. water bath. Then shake to dislodge the sediment and read the reactions macroscopically and under a scanning lens.

*After Lester J. Unger, New York City.

$\underline{-\vert}$ means that the original test was negative and
–
also the Coombs test (in the box).

$\underline{+\vert}$ means that the original test was negative and
–
the Coombs test was positive (in the box).

Positive and negative controls must be run at the same time as the unknowns.

The glassware must be clean and **dry.** Conglutinin, present in the testing serum, is sensitive to dilution with aqueous solutions and dissociates into its various serum protein components.

The blood specimens must be fresh or properly stored in a refrigerator. Avoid freezing or exposure of the blood to warm temperatures. Do not use specimens diluted with aqueous solutions.

Temperatures of the water bath may be as high as 40° C., but above this the red cells are damaged and the reactions are weak.

Avoid vigorous centrifuging.

Sources of error: Wiener has given the following sources of error in performing the saline agglutinating tests for Rh factors:

1. Poor blood samples:

(a) Whole blood keeps well for 5-7 days when refrigerated and may be taken either as a clot or mixed with dry oxalate. The blood suspensions do not keep and must be made fresh. The cell suspensions may deteriorate in warm weather within a few hours.

(b) Hemolyzed blood should not be used. Do not use wet syringes or alcohol in the syringes, and avoid too hot or too cold apparatus.

(c) Blood obtained by inadequate finger puncture may be mixed with tissue juices and gives poor results.

(d) Infected blood samples give weak reactions or false (bacteriogenic) clumping.

(e) When in doubt obtain a fresh blood sample by venipuncture.

2. Too weak a blood cell suspension gives poor results, as does too strong a suspension.

3. Use 7-8 mm. tubes, since wider tubes favor evaporation and the reactions are likely to be indistinct. Too narrow tubes are difficult to manage.

4. Maintain a constant 37° C. water bath. Lower temperatures give weaker reactions, and too high temperatures damage cells and serum.

5. Handle the tubes gently since rough handling breaks up the reaction. Roll or twist the tubes to dislodge the sediment but do not shake. When possible read the reactions in the original tube.

6. Take care not to mistake swirls of cells and small clots for agglutination. In true positive reactions the cells are strongly clumped with only a few free cells between the clumps.

7. Do not use citrate solution for preparing the blood cell suspension. Use physiologic saline.

8. Soapy, dirty, or old etched tubes must be avoided. Use only scrupulously clean tubes.

9. Use round-bottom or conical tubes only.

10. Do not use contaminated or outdated sera.

11. Always include at least one known positive specimen and one known negative specimen as controls.

Rapid mass Rh_o typing with bromelin—Pirofsky, Nelson, and Pittenger[144]

Bromelin consists of a group of proteolytic enzymes obtained from the pineapple stem. Under the trade name Bromezyme, it is commercially available* ready for use.

Standard bromelin solution:

1. Prepare a 0.5% bromelin solution by dissolving 0.5 gm. bromelin in 90 ml. physiologic saline and 10 ml. Sørensen phosphate buffer, 0.15M, pH 5.5.
2. Add 0.1% sodium azide and 0.05% actidione as preservatives.
3. Store at 4° C. Prepare fresh solutions monthly.

The commercial preparation may be used in place of this formula.

Procedure:

1. Mix 1 part anti-**Rh₀** conglutinating (slide test) serum with 5 parts saline.
2. Place 2 drops of diluted antiserum in a 10 × 75 mm. tube.
3. Add 1 drop of bromelin solution.
4. Insert a wooden applicator into the blood clot or oxalated whole blood and mix the adherent blood cells into the bromelin solution.
5. Shake for 30 sec. in a Kahn shaker.
6. Centrifuge **immediately** for 1 min. at 1000 r.p.m.
7. Examine macroscopically for agglutination or lack of agglutination, first gently dislodging the sediment. A positive reaction means that **Rh₀** is present on the unknown cells; a negative reaction means that the cells are negative for **Rh₀**.

Bromelin apparently functions by modifying the surface of the erythrocytes. Essentially identical results are obtained whether erythrocytes are pretreated with bromelin and the bromelin then washed from the test system or if bromelin is present in the test system. False positive bromelin reactions in systems that did not contain erythrocyte antibodies were seen at the following concentrations: bovine albumin 15%, human albumin 12.5%, electrophoretically pure gamma globulin 5%, polyvinylpyrrolidone 1.25%, and dextran 1.5%.

DETECTION OF Hr FACTORS IN BLOOD CELLS

If Hr tests are to be made, remember that these will always be positive on Rh-negative persons; therefore, to conserve anti-Hr sera it is best to wait for the results of the Rh tests before making Hr tests.

---

*Specific Serums, Inc., Hoboken, N. J.

After a blood sample has been classified into one of the Rh blood types (p. 1517), selected Hr tests are made with the aid of anti-Hr sera. In order to avoid unnecessary Hr testing and to conserve the valuable Hr antisera, only bloods of Rh_1 and rh′ need be tested with anti-**hr′** serum, and likewise only bloods of types Rh_2 and rh″ need be tested with anti-**hr″**. (There are exceptions to this, for example, bloods containing $\overline{\mathbf{R}}\mathbf{h}_0$ and $\overline{\overline{\mathbf{R}}}\mathbf{h}_0$.) By using these antisera along with the various anti-Rh sera, the Rh-Hr subtypes are designated as follows:

Rh_1, hr′ negative is called $\mathrm{Rh}_1\mathrm{Rh}_1$.
Rh_1, hr′ positive is called $\mathrm{Rh}_1\mathrm{rh}$.
rh′, hr′ negative is called rh′rh′.
rh′, hr′ positive is called rh′rh.
Rh_2, hr″ negative is called $\mathrm{Rh}_2\mathrm{Rh}_2$.
Rh_2, hr″ positive is called $\mathrm{Rh}_2\mathrm{rh}$.
rh″, hr″ negative is called rh″rh″.
rh″, hr″ positive is called rh″rh.

The above designations are phenotypes and not genotypes. (See Table 314, p. 1495.)

Anti-Hr testing sera are fortified with bovine albumin. Despite this fortification, umbilical cord blood or blood from newborn infants not infrequently give weak reactions because of their low concentration of conglutinin. In such cases, if in doubt, centrifuge the blood sample, remove the plasma, and replace it with an equal volume of compatible normal adult plasma; then resuspend the cells and proceed with the test. This method will also help eliminate doubtful reactions due to pseudoagglutination occurring with blood from patients who have certain hyperproteinemic states, such as myeloma, or in diseases associated with a high fibrinogen content of the blood, such as pneumonia and pregnancy.

Retest all negative and weak reacting bloods by the tube method, using anti-Hr agglutinating sera when available.

Open slide method for Hr factors

1. Prepare oxalated whole blood as directed on p. 1464.
2. Obtain slide sera (conglutinating sera), anti-**hr′** and anti-**hr″**.
3. Prepare 2 slides by marking them with a large oval, using a red wax pencil. Label properly.
4. Place 2 drops of oxalated whole blood on each slide.
5. Add 1 drop of anti-**hr′** serum to one slide and 1 drop of anti-**hr″** serum to the other.
6. Mix each with a separate applicator and spread over the area of the oval.
7. Place on a preheated lighted viewing box and rock back and forth for 2 or 3 min. Do not allow to dry.
8. Add a drop of saline after the reaction has had time to take place and let it run down the specimen. If rouleaux are present, they will break up. Read after the addition of the saline.
9. Report clumping as positive and lack of clumping as negative.

For results possible, see Table 327.

Tube method for Hr factors using ficinated cells

The test for the **hr′** and **hr″** factors in blood cells employs the rapid ficinating technic (Wiener).

1. Prepare a cell suspension in saline in the usual manner (p. 1463), wash twice with saline, remove the supernatant fluid after the last centrifugation, and resuspend the cells in saline to a 3-5% concentration.
2. Place 2 drops of this suspension in each of 2 Kahn tubes.
3. Add 1 drop of diluted ficin (1% ficin diluted 1:5, p. 1463) to each tube.
4. Mix thoroughly and place in a water bath at 37° C. for 15 min.
5. Mix again, wash once in saline, centrifuge, and remove and discard the supernatant fluid.
6. Add 1 drop of anti-**hr′** agglutinating (tube) serum to the first tube and 1 drop of anti-**hr″** agglutinating (tube) serum to the second tube.
7. Mix thoroughly and place the tubes in a water bath at 37° C. for 30 min.
8. Read reactions by tilting the tubes and observing for clumping or lack of clumping. A pear-shaped sediment when the tube is tilted shows lack of agglutination. Gently dislodge the sediment and examine under a scanning lens of a microscope or with a hand lens.

If the anti-**hr′** serum causes agglutination of the cells, **hr′** factor is present.

If the anti-**hr″** serum causes agglutination of the cells, **hr″** factor is present.

Table 327. *Possible results in Hr slide testing*

*Anti-**hr′** serum plus whole blood*	*Anti-**hr″** serum plus whole blood*	*Conclusions*	*Second half of phenotype symbol*
–	–	**hr′** and **hr″** negative	$\mathrm{rh_y}$ or $\mathrm{Rh_z}$
+	–	**hr″** negative, **hr′** positive	rh″ or Rh_2
–	+	**hr′** negative, **hr″** positive	rh′ or Rh_1
+	+	**hr′** and **hr″** positive	rh or Rh_0

If the cells do not agglutinate in either serum, neither **hr′** nor **hr″** factor is present. Refer to Table 327.

Tube test for Hr factors using untreated cells

1. Prepare 1 tube for each antiserum.
2. Place 1 drop of 2 or 3% saline suspension of unknown washed cells in each tube.
3. Add 1 drop of anti-**hr′** agglutinating (tube) serum to one tube and 1 drop of anti-**hr″** agglutinating serum to the other tube.
4. Mix the contents of each tube separately and incubate in a water bath at 37° C. for 1 hr.
5. Read the sediment in the bottoms of the tubes by slanting the racks; then read over a lighted box and under a scanning lens of a microscope.
6. Report clumping as positive and lack of clumping as negative.

If the cells clump in anti-**hr′** serum, the blood is **hr′** positive. If they fail to clump with anti-**hr′** serum, the blood is **hr′**-negative.

Clumping with anti-**hr″** serum means the blood is **hr″** positive, whereas lack of clumping in this antiserum means that the blood is **hr″** negative. Refer to Table 327.

It is not necessary to make Hr tests on Rh-negative blood since it will be **hr′** and **hr″** positive. Similarly, it is usually unnecessary to test blood containing **rh′** and not **rh″** for the **hr″** factor, except in cases in which an examination for $\mathbf{hr}^{S}$ is being made.

If a blood is **rh″** positive and **rh′** negative, it is not necessary to test for **hr′** because the reaction will be positive. Since the anti-Hr sera are in short supply, they should not be wasted by making unnecessary tests. Exceptions exist. See $\overline{\text{Rh}}_0$ and $\overline{\overline{\text{Rh}}}_0$.

To determine phenotypes in the Rh-Hr system, consult Table 314, p. 1495.

DETECTION OF OTHER Rh-Hr FACTORS IN CELLS

Test for Rh^{A}, Rh^{B}, Rh^{C}, Rh^{D} and their variants in blood cells—Wiener–Unger

1. Prepare a 1% solution of ficin in phosphate buffer as directed on p. 1463.
2. Dilute the ficin 1:5 (1 part ficin + 4 parts saline). **CAUTION: Ficin is a potent proteolytic enzyme. Therefore, do not allow the powder to come into contact with the skin or eyes. If the powder should get onto the skin, wash under running water for a few seconds.**
3. Prepare a 3-5% suspension of blood cells to be tested, wash twice with saline, and resuspend to a 3-5% suspension.
4. Transfer 1 drop of washed cells to each of 4 small Kahn tubes (7-8 mm. inside diameter).
5. Add 1 drop of diluted ficin solution to the cell suspension and mix.
6. Place in a water bath at 37° C. for exactly 15 min.
7. Wash once with saline to stop the action of the enzyme and remove and discard the supernatant fluid. This leaves the ficinated red blood cells in the tubes suspended in 1 drop of saline.
8. Add 1 drop of the antiserum, anti-$\mathbf{Rh}^{A}$, anti-$\mathbf{Rh}^{B}$, anti-$\mathbf{Rh}^{C}$, or anti-$\mathbf{Rh}^{D}$, to their respective tubes and mix.
9. Place in a water bath at 37° C. for 1 hr.
10. Read by observing the sediment in the bottom of the tubes in the usual manner. If the cells have not clumped, they will slowly flow down the tube in a pear-shaped pattern. If they have clumped, they retain their round shape or occasionally the top will fold over. After taking readings from the bottom of the tube, confirm by reading under a scanning lens of a microscope after gently dislodging the sediment.

If the cells have clumped, they contain $\mathbf{Rh}^{A}$ (or any of the other antigens, depending on the specificity of the antiserum) as well as $\mathbf{Rh}_0$. Such cells are simply designated Rh_0 (Rh). If any test is negative, the missing factor is indicated by the use of the appropriate small letter, for example, Rh^{a}, Rh^{b}, etc.

Test for rh^{w} factor in blood cells

Tests for $\mathbf{rh}^{w}$ are made only on cells containing factor **rh′** (Rh_1, rh′, Rh_z, $\mathfrak{R}\text{h}_1$, $\mathfrak{R}\text{h}_z$, and rh_y).

1. Wash once with saline and resuspend to a 2 or 3% concentration in saline.
2. Place 1 drop of saline-suspended cells in a small tube (inside diameter 7 mm.).
3. Add 1 drop of anti-$\mathbf{rh}^{w}$ serum and mix.
4. Place in a water bath at 37° C. for 1 hr.
5. Centrifuge at 500 r.p.m. for 1 min.
6. Gently dislodge the sediment and read macroscopically and under a scanning lens of a microscope. Report clumping as positive and lack of clumping as negative.
7. At the same time run controls, using cells positive for the $\mathbf{rh}^{w}$ factor.

If the unknown cells are clumped by the anti-$\mathbf{rh}^{w}$ serum, they contain the $\mathbf{rh}^{w}$ factor.

If the unknown cells fail to clump in the anti-$\mathbf{rh}^{w}$ serum, they do not contain the factor.

The distinction between positive and negative reactions is generally clear-cut. If desired, centrifuge for 1 min. at 500 r.p.m. and read again.

Because the anti-$\mathbf{rh}^{w}$ sera that are now available are of low titer, it is not recommended that this test be made in medicolegal cases.

Chapter 76

Detection of anti-Rh in blood serum (sensitivity tests)

ADDINE G. ERSKINE

As already pointed out, 2 distinct types of antibody might be formed in blood serum as a result of isosensitization with the Rh agglutinogen: (1) an Rh agglutinating antibody, which clumps cells when they are suspended either in saline or in a high protein medium, and (2) an Rh conglutinating antibody, which coats the cells without clumping them. These are called blocking antibodies because of their in vitro action of preventing agglutination. These antibodies are described on p. 1512. When the cells are suspended in their own plasma or in a fortified protein medium, this conglutinating antibody will cause them to clump. Bovine serum albumin, antihuman globulin, and other media will activate the blocking antibodies. Serum albumin also has the power to cause the blocking antibody to bring about clumping.[145] The mechanism by which serum albumin fractions exert their effects is not entirely clear.

BLOCKING ANTIBODY AND THE PROZONE PHENOMENON IN HUMAN ANTI-Rh SERUM

Wiener and Peters[146] showed that sensitization of Rh-negative individuals against the Rh factor can often be detected by in vitro tests for anti-Rh agglutinins in the serum. However, it was found[133, 147] that there were many Rh-negative patients, strongly sensitized to the Rh factor, whose plasma did not contain demonstrable anti-Rh agglutinins. These patients either had intragroup hemolytic transfusion reactions or had delivered babies with erythroblastosis fetalis.

In searching for an explanation of the lack of in vitro agglutination by these sera, Wiener mixed the sera with group O Rh-positive cells and later added known anti-Rh serum to the same test cells. The cells were not agglutinated by the known anti-Rh serum after they had been in contact with the patients' sera. He concluded that the action of the active agglutinin in the added serum had been blocked, and designated such antibodies as were present in these patients' sera as blocking antibodies. Fig. 494 is a diagrammatic representation of the difference between Rh agglutination and blocking reactions.

Tests were carried out on a number of patients with erythroblastotic infants on whom the usual tests for anti-Rh agglutinins were unsuccessful, and in most of the cases clear-cut blocking reactions were obtained, demonstrating the presence of a special type of Rh antibody. The reaction is specific in that it is obtained only with sera from Rh-negative individuals sensitized by the Rh factor and not with sera from Rh-positive or Rh-negative individuals not sensitized by the Rh factor.

A number of human anti-Rh sera have been obtained which exhibit a marked "prozone" effect.[148, 149] Taylor et al.[148] attempted to explain the behavior of such sera on the basis of optimal proportions of antigen and antibody. This does not explain why the phenomenon does not occur more frequently. Wiener's experiments indicate that such prozone phenomena are due to the presence in sera of a mixture of blocking and agglutinating antibodies, the agglutinating antibodies being of a higher titer.

Those sera that exhibit the prozone effect cannot be used as diagnostic reagents unless the agglutinin is far more active than the blocking antibody. Experiments seem to indicate that some of these sera can be absorbed

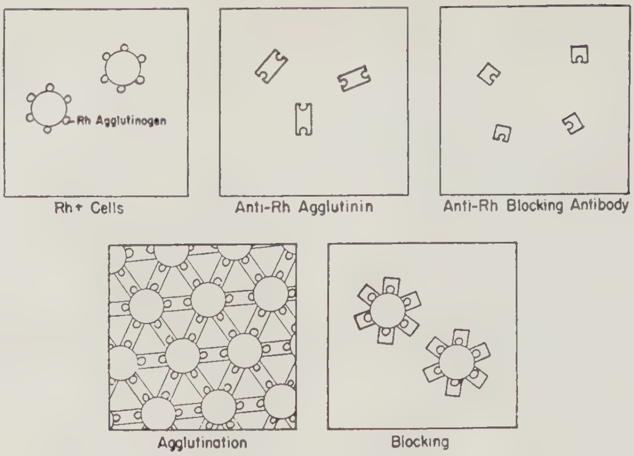

Fig. 494. Diagrammatic representation of Rh agglutination and blocking reactions. (From Wiener, A. S.: Am. J. Clin. Path. 15:106, 1945.)

with Rh-positive blood, so that after the blocking antibody is specifically removed the treated serum becomes a useful diagnostic reagent. From a practical standpoint, the significance of these findings lies in the fact that the characteristics of the agglutinating antibody and the blocking antibody are sufficiently clear-cut, so that, for example, there is no difficulty in the use of an anti-Rh serum which contains an anti-**rh′** agglutinin and also an anti-**Rh**$_0$ blocking antibody. In fact, Wiener has prepared anti-**rh′** reagents from anti-**Rh**$'_0$ sera by adding anti-**Rh**$_0$ blocking antibody.

It is often necessary to determine the presence in the patient's blood serum of Rh-Hr and other antibodies. Three tests are commonly made: (1) the agglutination test, (2) the blocking test, and (3) the conglutination test. These tests are made simultaneously and are referred to as "sensitivity" tests.

Sensitivity tests for Rh-Hr and other antibodies should be made of the sera of both the patient and the donors. These should be routine tests even if the cross-matching tests are compatible. If antibodies are present, they could be responsible for posttransfusion intragroup reactions should the patient be transfused with cells containing antigens for which these antibodies are specific. As an example, if the patient has anti-**hr′** and is transfused with blood having the **hr′** factor, a transfusion reaction might result. For further discussion refer to p. 1507.

A number of biological houses have made available to the public preserved cells containing all the rare antigens. These are called "Hemantigen,"* Type-A-Cells, and Panel Cells* or they are known by other names. Included in these specially selected human red cells are all the Rh-Hr antigens, and, in addition, **K-k**, **Fy**^{a} and **Fy**^{b}, **Le**(a+) and **Le**(b+), **Jk**^{a} and **Jk**^{b}, **M**, **N**, **S**, **s**, **P**, **Lu**^{b}, **Yt**^{a}, **U**, **Vel**, and others. By use of these cell panels one can detect the presence of antibodies without actually identifying them. If the exact identification of an antibody must be known, then a whole battery of specific antigens must be at hand, and the serum must be tested against each antigen.

The tests for antibody content of unknown serum is made as an aid in the management of pregnant women, as a means of predicting and preparing for the treatment of an erythroblastotic infant and as an aid in the search for prospective donors of Rh-Hr antibodies. In the method that follows, tests are limited to detection of the 5 principal Rh-Hr antibodies: anti-**Rh**$_0$, anti-**rh′**, anti-**rh″**, anti-**hr′**, and anti-**hr″**. Group O cells are used because they contain neither A nor B agglutinogen. Type Rh$_z$Rh$_0$ cells are used because they react positively with all 5 standard Rh-Hr antibodies.

Tests for Rh-Hr antibodies in serum (Fig. 483)

Have at hand group O Rh$_z$Rh$_0$† cells. Group O is used because the unknown serum might contain anti-**A** or anti-**B** agglutinins which would react with cells derived from groups A, B, or AB but not with group O. Type Rh$_z$Rh$_0$ cells are selected because they react with anti-**rh**′, anti-**rh**″, anti-**Rh**$_o$, anti-**hr**′, and anti-**hr**″ antibodies.

---

*Knickerbocker Laboratories, New York, N. Y.

*Certified Blood Donors Service, Inc., Jamaica, L. I., N. Y.

†The symbol Rh$_z$Rh$_0$ includes both Rh$_z$rh and Rh$_1$Rh$_2$, just as the symbol A includes both A$_1$ and A$_2$.

1. Prepare 2 cell suspensions of group O Rh$_z$Rh$_o$ cells:
   (a) Untreated and saline-suspended, 3% concentration.
   (b) Trypsinated or ficinated, 5% concentration.
2. Use 2 tubes, 7.5 cm. × 8 mm., for each serum tested (p. 1463).
3. Place 1 drop of untreated saline-suspended group O Rh$_z$Rh$_o$ cells in the first tube and 1 drop of group O Rh$_z$Rh$_o$ trypsinated or ficinated cells in the second tube.
4. Add 1 drop of the serum to be tested to each tube and shake.
5. Incubate in a water bath at 37° C. for 30 min.
6. Tilt the tubes back and forth gently over a lighted viewing box and observe for clumping or lack of clumping. Read under a scanning lens of a microscope.

If any tube appears to have clumps, the individual is sensitized and has antibodies against the Rh-Hr factors. If all tubes appear to be negative, proceed with the antiglobulin test.

Antiglobulin tests (indirect Coombs test)

Antiglobulin tests are made on negative-reacting untreated and trypsinated cells, saline-suspended.

1. Add saline to each tube to full capacity and mix thoroughly.
2. Centrifuge to pack and pour off the supernatant saline.
3. Shake and add more saline, centrifuge, remove saline, and shake again. This is the second washing.
4. Add more saline, mix, and centrifuge to pack the cells firmly. Pour off the supernatant saline and strike the lip of the tube upside down against a gauze pad to remove all traces of saline.
5. Shake to dislodge the cells.
6. Incubate at 37° C. for 5 min.
7. Add a drop of antihuman globulin serum (Coombs serum) to each tube.
8. Mix and centrifuge at 500-1000 r.p.m. for 2 min.
9. Gently dislodge the sediment, tip back and forth, and read under a scanning lens of a microscope.

Note: Unger performs Coombs tests on all negatively reacting specimens using ficinated cells. This is the **Unger test,** also called the **ficinated cell-antiglobulin test,** and is very important.

If clumping occurs, the individual is sensitized and has an antibody in the serum specific for a factor present in the clumped cells. Its specificity remains to be determined. If clumping occurs with saline-suspended cells without the addition of antiglobulin serum, there are agglutinating or bivalent antibodies in the serum. If it occurs with enzyme-treated cells or upon the addition of antiglobulin serum but not with saline-suspended cells, univalent (or blocking) antibodies are present.

If any clumping occurs, this must be reported. If it occurs with the donor's serum, reject the donor. If it occurs with the patient's serum, report to the director of the laboratory and prepare for identification and titration of antibodies.

If no group O Rh$_z$Rh$_0$ cells are available, use groups O Rh$_1$, O Rh$_2$, and O rh untreated, saline-suspended cells, also trypsinated cells. Make Coombs tests on negatively reacting specimens in tubes containing both untreated and trypsinated cells (Unger test). Unger also makes antiglobulin tests when ficinated cells have been used and negative results are obtained.

Test for Rh-Hr and rare antibodies in serum—sensitivity testing using cell panels

The same method may be carried out (see above), except that cells containing all the antigens are used. These are available commercially either untreated or as enzyme-treated cells. Untreated and enzyme-treated specific antigen cells are also available for cases in which it is necessary to identify the antibody. The method of using is the same as that above or in the following procedure.

Test for antibodies in serum using cell panels

In order to make complete tests for antibodies in an unknown serum, a suitable panel of known blood cells is necessary. These are cell suspensions containing known antigens and are derived from group O individuals. Such cells are available from a number of sources.*

1. Use a small tube (7 mm. inside diameter) for each group of antigens, and label the tubes with the identification of the antigens being tested.
2. Place 2 drops of the antigen cells in the properly labeled tube.
3. Add 2 drops of serum containing the unknown antibody.
4. Mix and centrifuge immediately for 1 min. at 1000 r.p.m.
5. Take a preliminary reading, recording clumping as a positive reaction and absence of clumping as a negative reaction.
6. Incubate the tubes giving negative reactions for 1 hr. at 37° C. If a cold agglutinin is suspected, incubate at 4° C.
7. Centrifuge the tubes for 1 min. at 1000 r.p.m. and read.

---

Test
Rh+ control
rh− control
Saline control
Washed cells of infant + Coombs serum
Washed ORh+ cells plus Coombs serum
Washed Orh− cells + Coombs serum
Washed cells of infant + saline

Fig. 495. Coombs test on cord or infant's blood (direct Coombs test).

8. Use the tubes that show a negative reaction. Wash the contents 3 times with saline, remove all traces of saline after the last washing, and add 1 drop of antiglobulin (Coombs) serum.
9. Mix, recentrifuge, and read. Agglutination of the cells in this step indicates that univalent antibodies are present in the serum.

Conglutination test for sensitivity to Rh-Hr factors—Wiener

The conglutination test requires that the cells be suspended in their own plasma or plasma-albumin mixture. To prepare the cells, make a 5% suspension of group O Rh_zRh_o (or other cells) in their own serum or plasma or in plasma-albumin mixture and carry out the test against the unknown serum as directed on pp. 1522 and 1523.

Indirect test for Rh_o blocking antibodies—Wiener

Procedure: Carry out the test in small Kahn test tubes. Use 1 drop of the patient's serum mixed with 1 drop of saline-suspended group O Rh-positive cells (Rh_o, Rh_1, Rh_2, or Rh_z).

1. Incubate for 1 hr. in a water bath at 37° C.
2. Centrifuge at 1000 r.p.m. for 1 min.
3. Read under a scanning lens.

If clumping occurs, Rh_o agglutinating antibodies are present in the unknown serum.

If the reaction is negative, centrifuge, remove the supernatant fluid, and add to the same tube 1 drop of known anti-**Rh**$_o$ agglutinating serum.

Mix and again place in a water bath at 37° C. for 1 hr., and read. Then centrifuge for 1 min. at 1000 r.p.m., shake gently, and take a second reading.

If agglutination now occurs, the patient's blood serum contains neither agglutinating nor blocking **Rh**$_o$ antibodies.

If no agglutination occurs, the patient's serum contains **Rh**$_o$ blocking antibodies; otherwise the known Rh-positive cells would have reacted with the added known anti-**Rh**$_o$ serum.

This same test may be used to detect other blocking antibodies, using specific cells in the original test and a specific antiserum when the initial reaction is negative.

Direct Coombs test—direct antiglobulin test on cord blood and infant's blood (for univalent antibodies derived from the mother)—Wiener[150-152]

The antiglobulin or direct Coombs test is used routinely whenever antibodies that react to antihuman globulin addition are to be detected. These are the univalent or blocking antibodies. These antibodies are also detected by the blocking, conglutination, and enzyme technics.

As Wiener first pointed out, the direct antiglobulin test can be used to detect the presence of univalent (blocking) antibodies coating the red cells of erythroblastotic infants after birth.* These univalent antibodies, when present, have been derived from the isosensitized mother and are considered the cause of erythroblastosis fetalis. When they are found, the baby will generally develop clinical signs of erythroblastosis fetalis if left untreated, and an exchange transfusion should be performed, using Rh-negative donor blood (see pp. 1537ff).

Procedure:

1. Wash the baby's blood cells 3 times with saline. After the last washing and centrifugation, turn the tube upside down and strike the lip on a gauze pad to remove all the saline.
2. Resuspend the cells to approximately 2% suspension in saline.
3. Place 2 drops of washed saline-suspended cells in a scrupulously clean, dry, 7 × 70 mm. tube. See Fig. 495.
4. Add 2 drops of antihuman globulin (Coombs) serum.
5. If the cells have been strongly sensitized by the maternal antibodies, clumping will be-

---

*As Wiener pointed out, the coating of the baby's cells can also be demonstrated by the blocking and direct conglutination tests. See Wiener and Sonn[150] and Wiener and Wexler.[151]

come visible almost immediately. Examine over a lighted viewing box.

6. If there is only a weak reaction or if the reaction appears to be negative, allow the tube to stand at room temperature for 15-30 min.
7. Centrifuge at 500 r.p.m. for 2 min.
8. Observe for agglutination over a lighted viewing box and under a scanning lens.

Agglutination means that the infant's cells have been coated with blocking antibodies derived from an isosensitized mother. Lack of agglutination means that the baby's cells are not coated.

Controls: Controls are made in small tubes.

1. Two drops of infant's washed cells plus 2 drops of saline.
2. Two drops of saline suspended Rh-positive cells plus 2 drops of antiglobulin serum.
3. If desired, prepare Rh-positive cells by coating them with known blocking antibodies. Add 2 drops of 2% suspension of Rh-positive saline-suspended cells to 2 drops of known Rh conglutinating (slide) (blocking) serum. Incubate at 37° C. for 30 min. There should be no agglutination. Centrifuge and remove the supernatant saline and wash 3 times with saline. These are the coated cells. Add 2 drops of Coombs serum (antiglobulin). The cells should now clump.
4. Two drops of Rh-negative cells plus 2 drops of antiglobulin serum.

Handle the controls in the same manner as the test.

Tubes 1, 2, and 4 should give negative reactions.

The antihuman globulin serum may give a false negative direct or indirect reaction when the red blood cells are coated with a minimal amount of antibody. In such cases prepare a 1:5 dilution by adding 1 drop of antihuman globulin to 4 drops of saline and use 1 drop in the test.

Antihuman globulin serum (Coombs serum) is prepared by hyperimmunizing rabbits against human serum globulin or whole human serum. Nonspecific antibodies are absorbed from the serum by adding human red cells which have been washed 10 times with saline solution.

Indirect antiglobulin test (Coombs test) for detection of isoimmunization[152]

See Rh-Hr sensitivity testing, pp. 1522 and 1523.

Quantitative direct antiglobulin test—Wiener[153]

This is a test for measuring the degree of coating of red cells by antibodies from an erythroblastotic infant or a patient with hemolytic anemia.

1. Wash the red cells to be tested 4 times with an excess of saline, as for the simple direct antiglobulin test.
2. Titrate the antiglobulin (Coombs) serum in serial dilutions against these washed cells.
3. At the same time titrate the antiglobulin serum in serial dilutions against Rh-positive cells which have been maximally coated by sensitizing them with an anti-Rh conglutinating (slide test) serum having a titer well in excess of 16 units by the albumin-plasma method (p. 1530).
4. Calculate the percentage of coating of the unknown cells by dividing the titer of the antiglobulin serum for these cells by its titer for maximally coated Rh-positive cells and then multiplying by 100.

This method has been applied by Wiener to determine the relative number of antigenic points in the discoplasm for agglutinogens of different blood group systems. It is also applied in babies with erythroblastosis as an additional criterion of severity and in patients having acquired hemolytic anemia, in whom it has been found that the degree of coating is correlated with the clinical manifestations. Thus a rise in the degree of coating may be associated with a hemolytic crisis, whereas a decrease may presage a remission. In disseminated lupus erythematosus there is milder manifestation of autosensitization; this view is supported by the results of the quantitative direct antiglobulin test.

False negative reactions with antiglobulin serum—Coombs

False negative antiglobulin tests result from a number of causes. These may be summarized as follows:

1. Minute traces of serum or plasma in the test cells may result in false negative Coombs tests. All test cells must be thoroughly washed with saline to remove any human protein present. At least 10 vol. saline must be used for each washing, and the cells should be washed at least 3 times.

The glassware must be scrupulously clean since traces of dried blood left in the tubes in many cases will result in false negative antiglobulin tests.

To resuspend the cells after each washing, use either a piece of wax paper or Parafilm over the top of the tube when inverting it, or use a clean cork.

Cells must not be centrifuged excessively since such packed cells prevent removal of small amounts of protein into the saline wash solution.

2. Avoid the use of old cells. Wherever possible, use cells freshly obtained. Do not keep saline-suspended cells more than 24 hr.

3. Avoid using too weak a suspension of cells.

4. Avoid using outdated or deteriorated antiglobulin serum. This is a general precaution which must be taken with every antiserum used in blood grouping.

5. Always run positive and negative controls with each direct antiglobulin test. For such controls $\mathbf{Rh_o}$-positive cells must be coated with anti-$\mathbf{Rh_o}$

conglutinating (slide) serum, washed, and the antiglobulin test run simultaneously with the unknowns.

AGAMMAGLOBULINEMIA

Inhibition test for human globulin, using coated (sensitized) Rh-positive cells—Wiener[154-156]

Agammaglobulinemia was first described as a syndrome by Bruton[157] and later elaborated by Bruton et al.[158] Patients with agammaglobulinemia show complete or almost complete absence of antibodies from their serum, rendering them susceptible to recurrent infections. Their serum lacks the normal blood group isoagglutinins, as well as gamma globulin as detected electrophoretically. The other serum proteins may be within normal limits.

A test for agammaglobulinemia was devised by Wiener,[155] based on the ability of antihuman globulin sera prepared in rabbits to agglutinate human red cells coated with antibodies of human origin, such as Rh antibodies and autoantibodies. Since materials containing human gamma globulin can inhibit the reactions of such antiglobulin sera, this inhibition technic has been applied to detect the presence of human gamma globulin in patient's serum. The test can be performed quantitatively[156] by testing a series of progressively doubled dilutions of the material in question, at the same time carrying out parallel titrations with normal human serum as a control.

The sensitivity of the inhibition test for gamma globulin is inversely related to the titer of the antiglobulin serum used. If a low-titered serum is used, the inhibition titer will be high; the higher the titer of the antiglobulin serum, the lower the gamma globulin inhibition titer. Thus if the test is performed qualitatively only, the diagnosis of agammaglobulinemia could be missed.

Principle: The solution to be tested for the presence of serum globulin is mixed with absorbed antihuman globulin serum (diluted to have a titer of 10-20 units for maximally coated Rh-positive cells) and the mixture allowed to react in a water bath at 37° C. for 1 hr. Then a suspension of Rh-positive cells, coated with **Rh$_0$** univalent antibody, is added, and the mixture is allowed to stand for a second period of incubation, after which the reaction is read. Failure of clumping to occur indicates the presence of human serum globulin in the material being tested. Occurrence of clumping indicates the absence of human serum globulin.

Reagents:

1. Rh-sensitized cells.
   - (a) Prepare a 2% suspension of **Rh$_0$**-positive cells in saline.
   - (b) Wash once with saline solution and resuspend to 2% concentration.
   - (c) Mix with an equal volume of **Rh$_0$** antiserum containing univalent antibodies with a titer of approximately 100 units by the albumin-plasma method (p. 1530).
   - (d) Allow the mixture to react in an incubator or water bath at 37° C. for 45 min.
   - (e) Centrifuge at moderate speed.
   - (f) Discard the supernatant fluid.
   - (g) Wash the sedimented cells 4 times with large volumes of saline.
   - (h) Resuspend sensitized cells to an approximate 2% suspension in saline.
2. Antiglobulin serum.

   Antiglobulin serum is commonly referred to as Coombs serum and is available commercially. It is absorbed according to the requirements of the NIH before being packaged. This is diluted so as to have a titer of 10-20 units for the Rh-sensitized cells.

Procedure:

1. Prepare serial dilutions in saline of the serum to be tested and of normal serum in the same manner as for titrations, as given on p. 1529. Use dilutions of 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:512, etc.
2. Place 1 drop of each dilution in its respective small Kahn tube, properly labeled.
3. Add 1 drop of diluted antihuman globulin serum to each.
4. Incubate at 37° C. in a water bath for 45 min.
5. Add 1 drop of Rh-positive sensitized cells to each tube.
6. Shake the tubes and reincubate for 60-90 min. in a water bath at 37° C.
7. Shake gently and read the reactions macroscopically over a lighted viewing box and under a scanning lens of a microscope.

Results: Normal human adult serum completely inhibits agglutination in dilutions as high as 1:500 on the average, depending on the titer of the antiglobulin serum.

Normal human spinal fluid in Wiener's experiments inhibited the antiglobulin serum from reacting in dilutions of approximately 1:2 or 1:4, but this was expected because normal spinal fluid contains only about 30 mg.% protein in contrast to the 7 gm. protein found in normal human serum. Saliva showed inhibition ability to a slight degree; umbilical cord serum inhibited antiglobulin serum to the same titer as adult serum. Serum from horse, ox, and rabbit did not inhibit antiglobulin serum, and rhesus monkey serum weakened its reaction.

In cases of congenital agammaglobulinemia, inhibition titers of about $\frac{1}{50}$ the normal titer were obtained. This indicates the presence of only 20-30 mg. of gamma globulin/100 ml.

serum in such individuals rather than a complete absence of gamma globulin. Following treatment with gamma globulin there is a corresponding increase in the inhibition titer.

TITRATION OF Rh ANTIBODIES IN SERUM AND IDENTIFICATION OF SPECIFICITY—UNGER

In the case of Rh-negative pregnant women who have had previous transfusions or pregnancies, Rh antibody titrations should be made before the third month to determine whether antibody is being carried into their present pregnancies. When antibody is demonstrated, titrations should be made at monthly intervals until the seventh month and at biweekly intervals thereafter until the last month, when they should be made weekly. When the titrations at the third month do not demonstrate Rh antibody, no further studies need be made until the seventh month.

The appearance of antibody or a rising titer when antibody is demonstrated at the third month proves that immunity is stimulated and that the fetus is Rh positive. An unchanging or falling titer proves that immunity has not been stimulated; the fetus may be Rh positive or Rh negative. When there is a rise in titer, on the other hand, the fetus is invariably Rh positive.

Rh antibody titrations are made on bloods of all Rh-negative sensitized patients and on all other bloods as ordered. For example, serum from Rh-negative patients is titrated against (1) group O type Rh_1Rh_1 (if not available, use type Rh_1rh), (2) group O type Rh_2rh, (3) group O type rh′rh, (4) group O type rh″ rh, and (5) group O type rh (triple Rh negative). The serum of Rh-positive patients sensitized against specific Rh factors may also be titrated against these specific cells. Several biological houses have specific cells for titration purposes; if the antibody must be identified and its concentration determined, specific antigen cells are used in the titration.

If the patient lacks $\mathbf{Rh_0}$ but has **rh′**, the blood is not titrated against **rh′**. If the patient is sensitized against the Hr factors, the serum is titrated against Rh-negative blood, which contains **hr′** and **hr″**, and Hr-negative blood is used as a control instead of Rh-negative blood (Rh-negative blood is Hr positive).

Six titrations are run simultaneously in some instances, but a simplified method, p. 1532, is recommended for routine practice:

1. Saline agglutination titer for bivalent antibodies.
2. Trypsinated cell titer.
3. Indirect blocking antibody titer for univalent antibodies.
4. Antihuman globulin titer for univalent antibodies.
5. Albumin-plasma titer for univalent antibodies.
6. Trypsinated cell-antihuman globulin titer for univalent antibodies.

The serial dilutions used are 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, and 1:512. Additional dilutions are made if the titer is 512 or higher.

If the sensitivity tests made before the titration indicate a weak antibody titer, some of the tubes may be omitted.

Three racks of 10 holes and 4 rows are needed for the titration proper (2 for saline-suspended cells and 1 for trypsinated cells), and one rack is used to make the serum dilutions. A rack with 2 rows of holes may be used to make the dilutions. The technic of handling dilutions is extremely important; no traces of serum or of the various dilutions must be carried from one tube to another, since that would erroneously increase the titer. The same size drop of each dilution must be used.

The cells needed are listed above. One set must be untreated and suspended in saline to a 2 or 3% concentration; they are washed once and resuspended in saline. Trypsinated cells are prepared as usual (p. 1463), and resuspended to 3-5% in saline.

Albumin-plasma mixture:

1. Pool a number of groups O, A, and B plasmas.
2. Centrifuge and remove the clear plasma.
3. Measure 8 drops of 30% bovine albumin into a tube.
4. Rinse the dropper with the pooled plasma, discarding each dropperful of rinsing plasma.
5. Repeat this 2 or 3 times, depending on how much plasma is available. This is to remove the bovine albumin from the dropper without admitting any water or saline.
6. Using the same dropper, add 32 drops of the pooled plasma, giving a dilution of 1 part albumin to each 4 parts pooled plasma.
7. Mix the albumin-plasma mixture in and out of the dropper before using.

For the indirect blocking test, anti-$\mathbf{Rh_0}$ saline agglutinating tube test serum will be needed.

When the titrations have been prepared, the first row of tubes in the titration racks will contain serially diluted serum plus group O Rh_1Rh_1 cells; the second row, the serially

Mix. Carry 1 drop to each tube 9 and 20 drops to 1:512. Rinse dropper

Mix. Carry 1 drop to each tube 10. Save for further dilutions if necessary.

Fig. 496. Set-up for full titrations for Rh antibodies. (After Unger.)

diluted serum plus group O Rh_2rh cells; the third row, group O rh′rh cells (5 tubes unless a high titer is anticipated); and for the fourth row, the first 2 tubes will contain serially diluted serum and group O Rh-negative cells, and serially diluted serum plus group O rh″rh cells will be in the second half of the fourth row.

Rack 2 is used for the controls on the various cells suspended in saline, plus the albumin-plasma mixture, to make sure that these cells do not agglutinate in the albumin-plasma mixture without the patient's serum.

One drop of each serum dilution is used for each drop of cells.

Serial dilution of serum and technic of titration (Fig. 496): Dilutions and titrations are made at the same time so that the same dropper can be used throughout the procedure, ensuring uniform drops in each tube.

1. Rack up the 3 racks of tubes, 7.5 cm. × 8 mm., for the titrations. Be sure to label at least the first tube in each row. Use a different color wax pencil for the trypsinated cells titrations. When antiglobulin tests are carried out, each tube must be labeled.
2. Rack up a set of Kahn tubes in 2 rows of 10 tubes each for the serum dilutions.
3. Use serum, **not** plasma, for the titration whenever possible.
4. Place the serum in tube 1 of the front row of the dilution rack. Leave the other 9 tubes in that row empty. Label the tubes 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, and 1:512, respectively.
5. Fill all the back row of dilution tubes with saline. There are now 2 rows of Kahn tubes, the first row empty except for serum in the first tube and the second row of tubes filled with saline.
6. Put 1 drop of undiluted serum into each first tube of each row in the titration.
7. Using the same dropper, carry 20 drops from the first tube of serum to the second tube in the front row of the dilution rack.
8. Rinse the dropper with all the saline in tube 1 of the back row of dilution tubes and remove the discarded saline tube from the rack. Wipe off the excess saline with a gauze pad.
9. Put 20 drops of clean saline into each tube of the dilution rack, front row, beginning with tube 2 and using the same dropper, which has been rinsed with saline, held at the same angle.
10. Mix the contents of tube 2 thoroughly in and out of the dropper, avoiding bubbles.
11. Transfer a drop of this dilution into each second tube of the titrations, holding the pipet at the same angle throughout and being careful not to add bubbles, for these are not full drops.
12. Carry 20 drops of diluted serum from tube 2 to tube 3 of the dilution rack.
13. Rinse the dropper with the saline in the tube behind tube 2, using all the saline, and wiping off the excess on a gauze pad.
14. Mix contents of tube 3 thoroughly, in and out of this same dropper, carry a drop to each tube 3 in the titrations, and carry 20 drops to tube 4 in the dilution rack.
15. Rinse the dropper with the saline behind tube 3 and continue in the same manner as above until all dilutions have been made and all the tubes in the titration racks have received their respective diluted serum, 1 drop each.
16. Do not put any of the diluted serum in the control tubes that are run on the cell suspensions which are to receive albumin-plasma mixture.

Adding untreated saline-suspended cells:

1. Add 1 drop of untreated saline-suspended group O Rh_1Rh_1 cells to each tube in the front row of titration racks 1 and 2.
2. Add 1 drop of group O Rh_2rh untreated saline-suspended cells to each tube of the second row in titration racks 1 and 2.
3. Add 1 drop of group O rh′rh cells untreated and saline suspended into each tube of the third row of titration racks 1 and 2.
4. Add 1 drop of group O Rh-negative cells, untreated and saline suspended, into the tubes marked for these cells, the first 2 or 3 in row 4 of the titration racks 1 and 2. If full titrations are run, there will be 10, not 2 or 3, of these tubes.
5. Add 1 drop of group O rh″rh untreated saline-suspended cells to each of the tubes marked for these cells (in the right-hand side of row 4 of racks 1 and 2 of the titrations). Full titrations may be run on these if desired, requiring 10 tubes, which would mean 5 rows of tubes for racks 1, 2, and 3, instead of 4 rows.
6. Prepare the control cell suspension tubes in rack 2, or else use a separate rack. Add 1 drop of each cell type to its respective tube. These will not receive any serum.

Preparation for trypsinated cell titrations:

1. In rack 3 for the titrations add 1 drop of group O type Rh_1Rh_1 trypsinated cells to each of the front row of tubes.
2. Add 1 drop of group O type Rh_2rh trypsinated cells to the second row of tubes.
3. Add 1 drop of group O type rh′rh trypsinated cells to the third row of tubes.
4. Add 1 drop of group O type rh″rh trypsinated cells to the fourth row of tubes.
5. Add 1 drop of group O type rh trypsinated cells in the tubes marked for these cells in row 4.
6. Incubate all 3 racks, after mixing each tube, for 1 hr. in a water bath at 37° C. The bath should be covered with a white cloth to keep dust out of the tubes.
7. At the end of the hour examine the bottoms of the tubes but do not disturb rack 2, which is exactly like rack 1 up to this point (except for the controls). It will be used later for the albumin-plasma mixture. It must stand undisturbed.

Saline agglutination titer

Read the result in each tube of **titration rack** 1 under a scanning lens of a microscope, tilting the tube back and forth to resuspend the cells gently. The weakest dilution with a positive reaction is the titer. This gives the **saline agglutinating titer.**

Albumin-plasma titer—Wiener

1. Using a dropper with a fine capillary, remove all the saline from each tube in rack 2, beginning with the weakest dilution and working back to the strongest. Do not introduce any serum into the control tubes, which must be handled first. In other words, remove the saline from the control tubes, then begin with tubes 10 and remove the saline from each tube 10, then from each tube 9, then each tube 8, etc., down to tube 1.
2. Prepare the albumin-plasma mixture as directed (p. 1527), and while the dropper (this is a second dropper) contains the mixture, add 1 large drop of the mixture to each tube in titration rack 2, including the controls.
3. Shake the rack thoroughly. Incubate at 37° C. in a water bath for 1 hr.
4. At the end of the hour read under a scanning lens of the microscope, after looking at the bottoms of the tubes. Record clumping as positive and no clumping as negative.

Always read the controls first and use the negative control tubes for comparison when not sure of a negative reading.

The weakest dilution with a positive reaction is the **albumin-plasma titer.**

Indirect blocking antibody titer—Wiener

1. Using titration rack 1, remove the saline from each tube in the front row of tubes where there is a negative reaction. If the reaction is positive, this test is omitted. This test is for the indirect blocking reaction. Only the first row of tubes is used.
2. Add 1 drop of anti-**Rh**$_0$ saline agglutinating serum to each tube which shows a negative reaction, and **only to row 1 of the first rack.** This detects the **Rh**$_0$ blocking antibody.
3. Shake and replace the tubes in a water bath at 37° C. for 1 hr.
4. At the end of the hour read under a scanning lens, and record. The last tube showing a **negative** reaction is the titer.

Explanation: In the first hour the patient's serum was mixed with known Rh-positive cells. If these cells did not agglutinate, either the patient's serum did **not** contain bivalent (saline-agglutinating) antibodies or else it **did** contain univalent (blocking) antibodies, which simply coated the cells but did not agglutinate them. Known anti-**Rh**$_0$ agglutinating serum was then added, which has the ability to agglutinate Rh-positive cells. Since these Rh-positive cells did not agglutinate, they must have been coated with blocking antibody derived from the patient's serum, which prevented their clumping when the known anti-**Rh**$_0$ serum was added. If they had clumped, that would indicate that there were no blocking antibodies in the patient's serum.

This gives the **indirect blocking titer.**

Antihuman globulin titer—Coombs

1. Using rack 1, add saline to each negative tube in rows 2, 3, and 4 after shaking. Fill the tubes about ¾ full.
2. Centrifuge and pour off the supernatant fluid, catching the last drop on a gauze pad.
3. Shake each tube, add saline again, and again centrifuge. This is the second washing. Remove the saline, replace with fresh saline, centrifuge, and remove saline, this time tapping the tubes hard against a gauze pad to remove all traces of saline. Take care not to lose the cells. This is the third washing.
4. Shake the tubes and add a drop of Coombs serum (antiglobulin) to each tube.
5. Centrifuge for 2 min. at 500-1000 r.p.m. without incubation.
6. Read all tubes under a scanning lens of a microscope and report clumping as positive and lack of clumping as negative.

Read the controls first for comparison. The weakest dilution with a positive reaction is the **antiglobulin titer.**

This completes the tests on saline-suspended untreated cells.

Trypsinated cell titer—Morton-Pickles

At the end of the hour's incubation of rack 3 containing the trypsinated cells, read under a scanning lens. These tubes are handled not quite so gently as the untreated cells. Read the negative reactions first for comparison; then read the other tubes. Record clumping as positive and lack of clumping as negative. The weakest dilution with a positive reaction is the **trypsinated cell titer.**

Trypsinated cell-antiglobulin titer—Unger

1. Use all the tubes in rack 3 which give a **negative** reaction.
2. Wash 3 times with saline as directed above in the other tests.
3. After the last washing and packing, remove all the saline by tapping hard against a gauze pad, resuspend the cells, and add a drop of Coombs serum to each tube.
4. Centrifuge for 2 min. at 500-1000 r.p.m. and read the reactions under a scanning lens.

The weakest dilution with a positive reaction is the **trypsinated cell-antiglobulin titer.**

Reactions are recorded by Unger as ++s, ++, ++w, +s, +, +w, ±, and −.

++s means a solid clump which does not break up when being handled.

++ means not quite so solid a clump.

++w means the clump breaks up partially while handling.

The other reactions are gradations of this reaction.

Be very careful not to read false clumping due to settling of cells or to rouleaux formation.

All trypsinated cell tubes will at first give the impression of a positive reaction, but a true positive reaction does not entirely disappear during handling. The weak reactions might be difficult to read, but if they stand for a while at room temperature, the clumping returns.

The titer is the reciprocal of the last tube in which a positive reaction occurs (except in the indirect blocking reaction, where the titer is the reciprocal of the last negative reaction). See example, Tables 328-330.

On all tubes where 2 tests are made, for example a Coombs test made after the saline agglutination test is negative or an indirect blocking test after the saline test is negative, the results are recorded by Unger as follows:

$\frac{-\mid}{-}$ means the first test was negative but the second test was also negative (top results in the box).

$\frac{+\mid}{-}$ means that the first test was negative but the second test (antiglobulin, etc.) was positive.

Note:

For the indirect blocking result the box opens to the right: $\frac{\mid +}{-}$

For the antiglobulin test it opens to the left: $\frac{+\mid}{-}$

Examples: See Tables 328-330.

In the indirect blocking titration, the last **negative** is the titer. If O Rh_1Rh_1 tubes are negative, remove saline and add anti-**Rh_o** tube serum. On other negative tubes make a Coombs test.

When negative, make a Coombs test after washing 3 times with saline.

In this example, Tables 328-330, the titers are as follows:

1. Indirect blocking: zero units.
2. Saline agglutinating: zero units.
3. Antiglobulin, 64 units against Rh_2rh.
4. Albumin-plasma method, 64 units against Rh_1Rh_1 and 128 units against Rh_2rh.
5. Trypsinated cell method, 128 units against Rh_1Rh_1 and also against Rh_2rh, and 1 unit against rh′.
6. Trypsinated-antiglobulin method, 256 units against Rh_1Rh_1 and Rh_2rh.

Table 328. *Rack 1: Saline-agglutinating, indirect blocking, and antiglobulin titer* (after Unger)

O rh″rh	−	−	−	−	−						0
O rh	−	−									0

Table 330. *Rack 3: Trypsinated and trypsinated-antiglobulin titer* (after Unger)

	1	*2*	*4*	*8*	*16*	*32*	*64*	*128*	*256*	*512*	
O Rh_1Rh_1	++s	++s	++s	++	++	++w	+	+w	$\frac{+\mid}{-}$	$\frac{-\mid}{-}$	128-256
O Rh_2rh	+++	+++	+++	++s	++s	++	++	+s	$\frac{+\mid}{-}$	$\frac{-\mid}{-}$	128-256
O rh′rh	++w	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$						1
O rh″rh	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$						0
O rh	$\frac{-\mid}{-}$	$\frac{-\mid}{-}$									0

Note: If the serum gives a positive reaction against Rh-negative cells, an anti-**hr**′ or anti-**hr**″ antibody is present or some mistake has been made.

SIMPLIFIED TITRATION OF Rh ANTIBODIES IN SERUM FOR ROUTINE HOSPITAL USE

Although the foregoing method of titration and determination of specificity gives valuable information, routinely it is not necessary to conduct all 6 of the titrations; 3 should suffice: the saline agglutination titration method, the antihuman globulin titration method, and the trypsin-treated cell titration method.

When Rh-negative persons are sensitized by an Rh factor, the specificity of the antibody involved is usually anti-$\mathbf{Rh_0}$. Often anti-**rh′** is also present and far less frequently anti-**rh″**. For this reason it will suffice in routine practice to use untreated saline-suspended group O type Rh_zRh_0 cells and trypsinated saline-suspended group O type Rh_zRh_0 cells. Thus there will be only 2 rows of tubes for titrations and, in addition, the Rh-negative controls.

1. Make serial dilutions as directed under the method on p. 1529: 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, 1:128, 1:256, and 1:512.
2. While making the dilutions place 1 drop of each dilution in its respective tube of 3 rows of tubes.
3. Add 1 drop of untreated saline-suspended group O type Rh_zRh_0 cells to each tube in the first row and 1 drop of group O type Rh_zRh_0 trypsinated cells to each tube of the second row.
4. In the third row, which should have 10 tubes (5 dilutions each for the negative controls), add 1 drop of the untreated saline-suspended group O rh cells to the first 5 tubes and 1 drop of trypsinated saline-suspended group O rh cells to the second 5 tubes (1:1, 1:2, 1:4, 1:8, 1:16). These are to detect Hr antibodies.
5. Incubate all tubes for 1 hr. at 37° C. in a water bath.
6. Read the bottoms of the tubes, and also read the reactions under a scanning lens.
7. Carry out antiglobulin tests on all negative reactions: Wash 3 times with saline. Remove all traces of saline after the last washing, using the technic outlined above.
8. Shake each tube and add 1 drop of Coombs serum (antihuman globulin) to each.
9. Centrifuge at 500-1000 r.p.m. for 2 min. and read.

The reciprocal of the highest dilution giving a positive reaction is the titer. See Tables 328-330 for recording the results.

PREPARATION OF ANTI-Rh SERUM FOR TESTING PURPOSES FROM NORMAL MALE DONORS (HISTORICAL)*

Because of the difficulty of securing an adequate amount of anti-Rh serum from isoimmunized women, Wiener and Gordon[158a] suggested the manufacture of this serum by injecting normal male professional blood donors. Their theory was based upon the fact that injections of relatively minute amounts of solutions A and B group substances into individuals lacking the corresponding agglutinogens stimulated a pronounced rise in the anti-**A** and anti-**B** agglutinin titers in such individuals.

Their method of immunization for the preparation of anti-Rh agglutinating serum was as follows: Group O, Rh-positive blood of a definite specificity is mixed with an equal volume of sterile citrate solution. The blood used in all experimental work belonged to type Rh_2Rh_2. Four ml. of this 50% blood suspension were injected intravenously into each of a number of donors. After an interval of 4 mo. (the maximum survival time for transfused red blood cells) a second intravenous injection was given, and 10 days later blood was withdrawn for testing. Donors with a satisfactory titer of anti-Rh agglutinins were bled.

The original work comprised the injection of 9 donors. Of these, 4 showed no evidence of antibody formation, whereas 5 had anti-Rh agglutinins in their sera. In 2 donors the titers of anti-Rh agglutinins were very high, 200 and 600 units, respectively. By the method of exchange transfusion with type rh donors, 1500 ml. blood were removed from each man, and a satisfactory yield of testing serum was obtained.

For more recent statistics see Wiener.[159]

TEST FOR Hr ANTIBODIES IN SERUM

The test for Hr antibodies in serum employs ficinated hr′ and hr″ cells belonging to group O. It is not made on serum when the individual has an rh-negative gene, but patients or donors of types Rh_1Rh_1, Rh_2Rh_2, and others without the *r* gene may be tested. The rapid ficinated technic of Wiener is used.

Before making the test, determine first that the serum to be tested does not contain anti-$\mathbf{Rh_0}$, anti-**rh′**, or anti-**rh″** agglutinins (refer to pp. 1522ff).

Procedure:

1. Prepare suspensions of group O hr′ (Rh_2Rh_2), group O hr″ (Rh_1Rh_1), and group O rh (**hr**′ and **hr**″ positive) cells in saline, wash twice

---

*It is best to purchase these sera from United States Government licensed manufacturers.

Table 331. *Results possible when testing unknown serum for Hr sensitization*

	hr″ (Rh_1Rh_1) cells	*hr′ (Rh_2Rh_2) cells*	*rh cells*	*Conclusions*
Unknown serum	−	+	+	hr′ sensitization
Unknown serum	+	−	+	hr″ sensitization
Unknown serum	−	−	−	No hr′-hr″ sensitization
Unknown serum	+	+	+	hr′ and hr″ sensitization

with saline, and discard the supernatant fluid after the last washing. Resuspend to 3-5% concentration in saline.

2. Place 2 drops of saline-suspended group O hr′ cells (Rh_2Rh_2) in a small Kahn tube properly labeled.
3. Place 2 drops of saline-suspended group O hr″ (Rh_1Rh_1) cells in a small Kahn tube properly labeled.
4. Place 2 drops of the saline-suspended group O rh (**hr′** and **hr″** positive) cells in a small Kahn tube properly labeled.
5. Add 1 drop of diluted ficin, 1:5 (p. 1463), to each tube and mix.
6. Place the 3 tubes in a water bath at 37° C. for 15 min.
7. Wash the contents of each tube once with saline, and after the last centrifugation remove and discard the supernatant fluid.
8. Add 1 large drop of the unknown serum to each tube.
9. Mix and place in a water bath at 37° C. for 30 min.
10. Read for agglutination or lack of agglutination, first gently dislodging the sediment. Read microscopically and under a scanning lens of a microscope or under a hand lens.

If there is no agglutination, wash the contents of each tube 3 times with saline, and after the last centrifugation remove and discard the supernatant saline. All traces of saline must be removed.

Add 1 drop of antiglobulin serum (Coombs) to each tube, shake, and centrifuge at 1000 r.p.m. for 1 min. Observe for clumping or lack of clumping after gently dislodging the sediment.

Results—to determine specificity of Hr antibody present: Assume that a patient belongs to phenotype Rh_1Rh_1. If there is no evidence of sensitization to **Rh**$_0$, **rh′**, or **rh″** as proved by previous tests, the following conclusions may be drawn from this test.

Rh_1Rh_1 cells have the **hr″** antigen; therefore, if these cells are not agglutinated by the unknown serum, the unknown serum lacks **hr″** antibody (as well as anti-**Rh**$_0$ and anti-**rh′**), and the unknown is not sensitized to **hr″**.

Rh_2Rh_2 cells have the **hr′** antigen; therefore, if these cells are not agglutinated by the unknown serum, the unknown serum lacks **hr′** antibody (as well as anti-**Rh**$_0$ and anti-**rh″**), and the unknown is not sensitized to **hr′**.

If the unknown serum reacts negatively with rh cells, there is no **hr′** or **hr″** sensitization and therefore no anti-**hr′** or anti-**hr″** agglutinins in the unknown serum.

If the unknown serum reacts positively against Rh_2Rh_2 cells and no **rh″** or **Rh**$_0$ sensitization has been shown by prior tests, then this serum has anti-**hr′** agglutinins.

If the unknown serum reacts positively against Rh_1Rh_1 cells and no **rh′** or **Rh**$_0$ sensitization has been shown by prior tests, then this serum has anti-**hr″** agglutinins.

If the unknown serum reacts positively against type rh cells, there is either **hr′** or **hr″** sensitization, or both. If there was no reaction against Rh_1Rh_1 (**hr″** positive) cells, but there was a positive reaction against Rh_2Rh_2 cells (**hr′** positive), and the positive reaction with type rh cells shows the presence of an **hr′** or **hr″** antibody, by subtracting **hr″** from **hr′** + **hr″**, this leaves **hr′** sensitization as proved by the test using Rh_2Rh_2 cells. The group O rh cells act as a control over the other 2 reactions.

This test shows specific sensitization of an Rh-positive patient to an Hr factor when no **rh′** or **rh″** sensitization has been shown to exist when testing the Rh-positive serum against rh′ and rh″ cells.

An individual with phenotype Rh_1Rh_1 gives the following reactions of cells against specific antisera:

Anti-**rh′**	Anti-**rh″**	Anti-**Rh**$_0$	Anti-**hr′**	Anti-**hr″**
+	−	+	−	+

and such an individual cannot be sensitized against **hr″** but can be sensitized to **hr′**. For possible results consult Table 331.

Chapter 77

Erythroblastosis fetalis

ADDINE G. ERSKINE

The discovery of the Rh factor supplied the key to 2 medical mysteries[160]*—the cause of hemolytic transfusion reactions in patients receiving blood of their own A-B-O group and the pathogenesis of erythroblastosis fetalis. The demonstration by Wiener of the existence of 2 forms of antibodies, the agglutinating or "bivalent" antibody, which reacts in saline media, and the blocking or "univalent" antibody, which reacts in high protein media, that is, the reaction takes place in saline and is detectable by the antiglobulin technic, led to new tests for the detection of isoimmunization. Since the original work of Landsteiner and Wiener in 1937, many different varieties of Rh factors have been discovered, as well as certain contrasting factors known as Hr factors and the factors of other blood group systems. It is now possible by testing the blood of the expectant mother and her husband and by carrying out antibody tests on the expectant mother's serum periodically during the pregnancy to predict not only what the newborn baby's blood type may be but also whether or not the baby is likely to have hemolytic disease.

Erythroblastosis fetalis is characterized by abnormal destruction and regeneration of erythrocytes. It is fair to assume that intravascular hemolysis or clumping, or both, initiates all the other pathologic changes in this condition. Much of the pathology depends upon an excessive destruction of erythrocytes and upon an attempt on the part of the body to compensate for this loss. Anemia, increased bilirubin in the blood and in various fixed tissues of the body, abnormal erythropoiesis in many organs, including the spleen and liver, and an increase in immature forms of erythrocytes in the circulating blood are among the signs most commonly observed.* The extreme edema present in some of these cases has not as yet been satisfactorily explained. Some have explained it on the basis of renal failure, injury of the general capillary bed, and a decrease in plasma proteins occurring in conjunction with cellular hemolysis.

The clinical and laboratory manifestations include jaundice, anemia, erythroblastemia, edema, hepatosplenomegaly, and purpura, varying widely in degree. The infant may have none, few, or all of these signs. The most severely affected infants are either stillborn or die shortly after birth. In those untreated babies who survive the immediate postnatal period there is almost invariably a steady rise in the concentration of the blood bilirubin, which is believed to occur because the liver of the newborn infant is unable to convert indirect into direct bilirubin.

According to Wiener and Wexler,[161] the clinical course of these babies can be predicted in only a general way. Those with severe anemia, petechiasis, high cord blood icterus index, edema, and hepatosplenomegaly generally die within a few hours or days with pulmonary hemorrhage after becoming extremely jaundiced. Postmortem examination in such cases will almost always show bilirubin staining of the basal nuclei of the brain, **kernicterus.** Other infants who appear less severely affected at birth, with a more moder-

---

*For a description of the blood picture in erythroblastosis fetalis, see p. 1295.

ate anemia, 10-14 gm.% hemoglobin, but who have an elevated cord blood icterus index, more than 16 units, will develop intense jaundice and similarly die within 3-5 days with nuclear jaundice. In this group some babies may survive, but because of brain damage they later exhibit retarded development.

Of the infants who appear to be more mildly affected (normal cord blood, blood hemoglobin, cord blood icterus index less than 16 units), so that life is not in jeopardy, nuclear staining may nevertheless still occur and some degree of cerebral damage may become manifest either during the neonatal period or later in life. All such affected infants should therefore be treated with exchange transfusion which to date is the only treatment that has been proved to save the lives of these babies and prevent neurologic sequelae.

There is a group of infants whose general condition remains good and whose jaundice never becomes intense enough to be a cause of concern. Such babies should be treated expectantly. It must be stressed, however, that in case of doubt it is better to perform an exchange transfusion than to leave untreated any baby who might sustain brain damage.

Effective methods have been devised for treating the affected erythroblastotic baby,[162] particularly the use of exchange transfusion. If the baby at birth is not already moribund or irreversibly damaged, it is generally possible to save him with exchange transfusion. In babies who survive it is possible almost invariably to prevent the occurrence of any neurologic sequelae. The success of treatment depends on the promptness and thoroughness with which it is carried out. If the prenatal tests indicate the likelihood of an erythroblastotic baby, a trained immunohematologist should be consulted during the pregnancy, to be available when the baby is born. Prophylactic treatment of the sensitized Rh-negative mother with so-called "Rh-hapten," diethylenesulfonate, progesterone, exchange transfusions of the mother, cortisone, and "desensitizing" injections of Rh-positive blood have been unsuccessful. The only treatment that has been successful to date is exchange transfusion of the affected baby. In this transfusion the baby's coated cells and some of his plasma containing univalent antibodies derived from the mother are removed while being replaced with erythrocytes which cannot be coated by the offending antibodies.

Although the great majority of cases of erythroblastosis fetalis are the result of $\mathbf{Rh_0}$ sensitization, not infrequently Rh-positive as well as Rh-negative mothers may have erythroblastotic babies because of A-B-O sensitization. In addition, sensitization has been found to be due to any of the numerous Rh-Hr factors, particularly **hr′**. Sensitization to blood factors of other blood systems, such as **Kell** (**K-k**), have been reported, and in rare instances there has been sensitization to factors **P**, **U**, $\mathbf{hr^S}$, **M**, and others. It is not always practicable for the laboratory to test specifically for sensitization to each of the factors, and for that reason sensitization tests of the mother's serum should be made using cell panels as well as cells containing all the Rh-Hr factors. Most of the cases, as stated above, result from $\mathbf{Rh_0}$ sensitization, and the other cases can be diagnosed after the baby is born by observing all newborn babies closely for evidence of early jaundice or anemia. When jaundice and anemia appear during the first or second day of life, immunohematologic tests are necessary in order to save the baby's life.

It is common practice today in many hospitals to perform a direct Coombs (antiglobulin) test on the cord or infant's cells as soon as the baby is born, and if the test is positive and if the cord bilirubin is significantly elevated, an exchange transfusion is performed. Often the physician will wait 8-12 hr. or longer to see what signs or symptoms develop, according to Wiener.[163] If the baby shows no **clinical** signs, for example, no jaundice and no anemia, an exchange transfusion is not performed.

The principal factor in determining the possible severity of the disease is the mother's antibody titer, because it in turn determines the degree of coating of the fetal cells (Table 332). Simple coating of the fetal red cells need not necessarily interfere with their function; not only must they be coated but conglutinin must also be present before clumping takes place. Although complement and complement-like substances are not fully developed before birth, if the mother's antibody titer has been high for sufficient time, the child may be stillborn or, if born alive, may manifest symptoms of severe erythroblastosis fetalis. Often the baby appears normal at birth, but early in the neonatal period symptoms appear.

There is no direct relationship between the depth of jaundice and the degree of anemia. The jaundice is hepatogenous as well as hemolytic in origin. In addition, although brain damage occurs more often in severely jaun-

diced babies, some severely jaundiced babies may recover completely and some with lighter jaundice may die, with brain damage. Wiener[164] believes that the tissue damage is due primarily to vascular injury resulting from intravascular conglutination of the baby's coated cells. Damage to the liver results in jaundice. Blockage of circulation in the brain produces nuclear damage and allows bilirubin to cross the blood-brain barrier and stain the dead and dying ganglion cells; therefore, if the coated cells are removed before intravascular clumping occurs and are replaced by cells that cannot be coated by the free antibody, tissue damage may be prevented. Tissue damage which may be present at birth appears to be largely reversible. Kernicterus is rarely if ever found in newborn or stillborn infants. This is to some degree probably due to the fact that bilirubin formed in utero passes into the maternal circulation and is largely excreted. The rapidly developing jaundice and organic injury are probably due to increase in the concentration of complement or conglutinin in the infant's circulation during the early neonatal period. This results in intravascular clumping and hemolysis.

HYPERBILIRUBINEMIA AS AN INDICATION FOR SECOND EXCHANGE TRANSFUSION

In a case described by Wiener,[165, 166] differential agglutination tests carried out after the exchange transfusion showed that there had been virtually a complete replacement of the baby's Rh-positive coated red blood cells by type rh cells. The principal purpose of the exchange transfusion had therefore been accomplished—to remove the baby's coated cells and to replace them with other red cells incapable of reacting with the Rh antibodies passively acquired by the baby by placental transfer from the mother. However, it is not sufficient merely to remove the baby's coated red cells, which cause the disease, because the disease process has a certain momentum and it may require a few days for the damage to be reversed. In the meantime, because of the poor liver function in the newborn infant, bilirubin may accumulate in the baby's body, and if the bilirubin concentration reaches a high enough level, irreversible brain damage may result. It is therefore necessary at times to carry out a second exchange transfusion to counteract the hyperbilirubinemia until such time as the baby's liver can cope with the bilirubin.

Wiener follows the bilirubin level by icterus index determinations rather than by the van den Bergh tests, using acetone precipitation of serum which also precipitates any contaminating hemoglobin. After centrifugation, the supernatant fluid is diluted with water and matched against a series of potassium dichromate standards. See p. 101, Dingee method. Icterus index values are converted into bilirubin concentration by dividing by 6. Brain damage rarely results before the icterus index exceeds 150-200 units, corresponding to a bilirubin level of about 25-30 mg.%. A figure of 120 icterus index units or about 20 mg.% of bilirubin would therefore be set as an indication for repeating an exchange transfusion, which leaves a safe margin of error.

In the case cited by Wiener the icterus index of the cord serum was 30 units as compared with a maximum normal value of approximately 15 units. The first sample of blood taken at the exchange transfusion 1 hr. later had an icterus index of 36 units, whereas a sample obtained at the end of the transfusion had an icterus index of 18 units. There was a drop of only about 50% in the icterus index value in contrast to the approximate 98% replacement of red cells in the exchange transfusion (2 units of blood were used). There were 2 reasons for this: (1) bilirubin is present not only in the blood plasma but also in the extravascular tissue spaces from which it diffuses into the circulation during the exchange transfusion and (2) the concentration of bilirubin is not static but dynamic. The bilirubin concentration, not only in erythroblastotic babies but in normal babies as well, tends to rise during the first 2-4 days of life.[167] Twenty hours after the exchange transfusion the icterus index in this case had risen to 60 units; at 44 hr. it was 100 units, and at 68 hr. it was 120 units. Preparations were therefore made for a second exchange transfusion. Two units of type rh blood, partially concentrated, were obtained. At 74 hr. and prior to the second exchange transfusion another sample of blood showed an icterus index of 144 units.

A second exchange transfusion was carried out by the radial artery–saphenous vein technic, using the blood vessels on the opposite side. About 800 ml. blood were injected over a period of 1½ hr. through the saphenous vein at the ankle while an equal volume was withdrawn from the radial artery at the wrist. The baby withstood the procedure well and was returned to the nursery in good condition though still deeply jaundiced.

A sample of blood withdrawn at the midway mark had an icterus index of 90 units, and the last sample taken at the exchange was only 72 units. The following morning the icterus index was only 78 units, and the baby appeared less jaundiced. The jaundice faded rapidly thereafter; after 48 hr. there was no discernible jaundice and the baby was sent home, to be followed at the office.

Some workers, in treating severely affected erythroblastotic infants, have given as many as 7 exchange transfusions on successive days, using only 1 unit of blood for each transfusion. However, there is only a slight drop in bilirubin concentration with a rebound often to a considerably higher level than before the exchange transfusion. Not every infant requires more than 1 transfusion.

AMOUNT OF ANTIBODY AND BILIRUBIN REMOVED BY EXCHANGE TRANSFUSION

The antibody level in a baby depends on the amount acquired from the mother by passive placental transfer since the baby does not produce any antibody. Such antibodies have been found[166] to have a half-life in the baby's circulation of approximately 30-35 days. In erythroblastotic babies the half-life may be less since newly formed Rh-positive cells can absorb the free Rh antibodies.

Wiener calls attention to the **rebound phenomenon**, that is, the rise in antibody titer back almost to the original level in the days following an exchange transfusion. Considering that the half-life of the Rh antibody is about 30 days, a titer of 12 units obtained when the baby is 1 mo. old represents a titer of at least 24 units at birth, especially since the increase in the baby's size would tend to dilute the antibody and lower the titer further. In one erythroblastotic baby the initial titer value was 44 units, and 2 exchange transfusions totaling about 8 times the baby's blood volume were given, which removed only approximately half the Rh antibodies. This gives some indication of the large size of the extravascular space containing free antibodies and presumably also bilirubin. The routine use of only 1 unit of blood for an exchange transfusion may not produce the desired effect, and in severely affected babies at least 2 units should be used.

EXCHANGE TRANSFUSION

As Wiener first showed, the pathognomonic serologic finding of Rh hemolytic disease is the positive direct antiglobulin reaction of the baby's red cells (direct Coombs test). In A-B-O hemolytic disease the direct antiglobulin test is negative or it may be only weakly positive. Maternal antibodies passing through the placental barrier become attached to fetal red cells, and these coated red cells are believed to initiate the disease process. Theoretically, therefore, removal of the baby's coated red cells and replacement by red cells incapable of combining with maternal antibody would be expected to arrest the disease process.

In 1944 Wiener et al. adopted a method of treating erythroblastosis fetalis by simultaneously withdrawing and injecting blood, a procedure that they designated exchange transfusion.[162, 168] Since in exchange transfusions blood is withdrawn at the same time that compatible blood is given, from the onset some of the transfused cells are removed. It is for this reason that an exchange transfusion involving a quantity of blood equal only to the baby's blood volume will be insufficient to accomplish a satisfactory exchange. A pint of blood (approximately 2 blood volumes) will accomplish an 85% replacement of red blood cells. Wiener prefers, except in the mildest cases, to use 2 pints of blood. In a baby of average size, with an approximate blood volume of 250 ml., this quantity will accomplish about a 98% replacement. Unger, on the other hand, prefers to remove, if possible, 80 ml. of the infant's blood before starting the exchange. He then exchanges only 1 unit of blood. He very rarely finds it necessary to do a second exchange.

A blood bilirubin concentration of 20 mg.% at any time during the first 72 hr. of life, as previously explained, may be regarded as an indication for repeat exchange transfusion, especially if the rate of rise indicates that even higher levels will probably be reached. An attempt is made to delay the second exchange transfusion as long as it is safe to do so and then, depending on the severity of the case, to use 2 or even 3 units of blood. When this method is followed, there has seldom been any need for a third exchange transfusion. Indications for a second exchange transfusion are usually evident by the time the baby is 24-48 hr. old. Serial determinations of blood bilirubin must be made as a guide for treatment, as explained on pp. 1536 and 1537.

Donor's blood: Obtain the freshest possible blood for the transfusion. It should never be more than 3 days old. In Rh hemolytic disease use Rh-negative blood, which must be compatible with either the baby's serum or with the maternal serum. Low-titered group O Rh-negative blood may also be used in all cases. Unger disregards the titer of anti-**A** and anti-**B** in the group O blood used because he first removes almost all of the supernatant plasma. It is best, however, to avoid depletion of the supply of group O Rh-negative donor blood, so that Rh-negative blood of the **mother**'s A-B-O group is used, since this is always compatible with the infant's serum, even when the baby is group O and the mother is group A or group B. Such blood can be prepared before the baby is born.

In cases of A-B-O incompatibility, low-titered group O blood is used. In the very rare instances in which the antigen responsible for the incompatibility is not immediately identified and the infant's clinical condition is desperate, the mother may be bled and her blood cells used to treat the baby.

Before the citrated blood is used for the exchange transfusion, it is concentrated to 450 ml. by withdrawing 100-150 ml. plasma after the blood has been allowed to sediment while standing in a refrigerator. Partially concentrated blood prepared in this manner has a hematocrit value of about 50%.

Procedure—Wiener-Wexler:

1. Immobilize the infant on a circumcision board by the use of flannel wrappings, leaving one arm and one leg free.
2. Strap down the foot with adhesive tape and expose the saphenous vein at the ankle through a transverse incision made anterior and superior to the medial malleolus.
3. Cannulate the vein with a 20-gauge spinal trocar and tie in place.
4. Inject 200 units heparin, diluted in 2 ml. saline, through the needle and attach a 3-way stopcock. This in turn bears the tubing from the blood reservoir as well as a 10 ml. Luer-Lok syringe for injection of the blood and the medication.
5. Before any injection of blood is made, isolate the radial artery through a transverse incision on the radial side of the wrist of the free arm just proximal to the head of the radius.
6. Expose the artery by gentle, blunt dissection. It can be readily recognized as a moderate-sized, plump vessel, the wall of which is a little thicker than that of the saphenous vein at the ankle.
7. Carefully clean the artery, lift up on a closed mosquito clamp, and open by making an angled incision through the flattened wall. The artery is not cannulated since this would impede the flow of blood.
8. Collect the blood in 30 ml. medicine glasses, which in turn are emptied into a 1 L. graduated container for final measurement.
9. To increase the efficiency of the exchange transfusion first bleed the infant of about 60 ml. before administering the blood.
10. Commence the injection of blood through the saphenous vein at a rate that keeps pace with the arterial flow and that makes up for the deficit produced by the initial bleeding by the time the 90 ml. mark is reached. Equal quantities of blood are administered and withdrawn.
11. During the procedure give a repeat dose of heparin at the 200 ml. mark and, if 2 units are used, at the beginning of the second unit.
12. Beginning with the 50 ml. mark, administer 1.5 ml. of 10% calcium gluconate solution for each 100 ml. blood given. Inject this directly into the venous trocar and immediately flush through with 10 ml. blood.
13. At the termination of the procedure close the incisions with fine silk sutures, which are removed on the fourth postoperative day. Pressure bandages control bleeding. Neither the artery nor the vein is ligated, and it may be assumed that they recannulate.

Postoperatively, place the infant into an Isolette for warmth. Oxygen may be given if needed. Prophylactic penicillin, 100,000 units every 8 hr. for 2 days, is the only routine medication used. Feedings are standard, and the more robust infants may be breast fed.

If the procedure is repeated, the opposite arm and leg are generally used. It is possible to recannulate the vein for the second transfusion, but the artery will not bleed freely again after it has been used for the first transfusion.

In Wiener and Wexler's experience no mortality that could be ascribed to the procedure itself has occurred with this technic. The only limitation to the speed with which the operation is carried out is the rate at which the blood flows from the arterial end. The shortest time for 1 unit of blood has been 25 min. and the longest 2 hr., in the experience of Wiener and Wexler. Since the inflow and outflow are always balanced, blood volume changes do not occur, and the babies appear to be quite comfortable throughout the procedure.

Wiener et al. have cautioned against the indiscriminate use of the umbilical catheter method of exchange transfusion, stating that it is a blind procedure and has been said to have caused damage to important intra-abdominal vessels with resultant thrombosis and embolism. Intra-abdominal hemorrhage, peritonitis, and splenic rupture have also been reported following its use. In view of these dangers, the assertion that the method is easier to perform is not sufficient justification for its use; moreover, this assertion is not in the strictest sense true, since not infrequently the umbilical vessels cannot be catheterized and operators have at times had to resort to incisions in the abdominal wall and groin in order to catheterize large vessels in those regions.

Booster transfusion: Wiener[160] has pointed out the need for a booster transfusion in cases in which the baby's plasma contains a high titer of free Rh antibodies. When there are free Rh antibodies in the baby's plasma, the baby's newly formed Rh-positive red cells may become partly coated, and when the baby is 3-4 wk. old, his blood may give a weakly positive direct antiglobulin (Coombs) reaction. This is generally harmless. Eventually the red cells will all be Rh positive and the direct antiglobulin test will become negative. However, when the Rh antibody titer is high, the baby's Rh-positive cells may be destroyed as rapidly as they are released from the bone marrow. Such babies may require a booster transfusion.

The most convenient donor to use for the booster transfusion is the mother, since her cells are always compatible. It is necessary, however, to remove the supernatant plasma containing Rh antibodies and to wash her cells with sterile saline solution. The father's blood cannot be used since he is Rh positive and his infused cells could become coated with the free antibodies in the baby's blood.

SENSITIZATION TO THE A-B-O FACTORS*

Halbrecht,[170] Polayes and McNally,[171] and Wiener et al.[172] called attention to cases of A-B-O sensitization in which the Rh factor had no part whatsoever. Mild cases of erythroblastosis due to A-B-O incompatibility appear to be quite common but are usually overlooked. Although most infants recover spontaneously, in some cases the manifestations are severe enough to warrant treatment.

It was noticed first by Rosenfield[173] that erythroblastosis due to A-B-O incompatibility is almost always confined to babies of group O mothers. This can readily be seen in earlier reports on series of cases by Wiener, Sonn, and Hurst and by Wiener, Wexler, and Hurst. Wiener and Unger showed that group O babies of group O mothers acquire by placental transfer about 16 times as much isoantibody as do babies having mothers of group A or group B. They concluded that this was adequate to account for the excess of group O mothers with babies having A-B-O hemolytic disease.

As explained elsewhere in this section (p. 1472), agglutinogens A and B are both characterized by factor **C**, so that there is no anti-**C** present in the sera of groups A, B, and AB. Group O erythrocytes are the only ones that do not contain the **C** factor, and therefore group O serum is the only variety that can have antibodies specific for factor **C**. These antibodies, Unger and Wiener showed,[174, 175] are usually of the univalent variety and therefore readily traverse the placental barrier. Thus, if the mother's blood is group O and that of the fetus is group A, the fetal erythrocytes have the **C** factor, whereas the maternal erythrocytes lack it, and anti-**C** may be formed in excess by the mother if the group A blood cells of the fetus enter the maternal circulation. These antibodies in turn traverse the placenta and enter the fetal circulation. Since these **C** antibodies cross react with both A and B agglutinogens, if these agglutinins are present in the baby's plasma in sufficient amount, they could produce hemolytic disease in the infant.

Wiener[176] concluded that (1) the A-B-O blood properties appear to be the most com-

---

*Refer to p. 1472 for discussion of factor **C** of the A-B-O blood groups.

mon cause of erythroblastosis in infants with Rh-positive mothers; (2) the natural anti-**A** and anti-**B** agglutinins in maternal sera, as a rule, have little or no harmful effect on fetuses belonging to groups A, B, and AB, because they usually are of low titer and avidity and because the natural isoagglutinins presumably are larger molecular aggregates which do not traverse the placenta easily; (3) individuals may become isosensitized against the A and B properties by the inadvertent transfusion of blood of an incompatible group, from pregnancy with a fetus of an incompatible group, or by injections of materials containing soluble group substances such as pooled human serum, therapeutic horse serum, etc.; (4) immune isoantibodies for A and B in the maternal serum (anti-**C**) are more dangerous for the fetus than the natural isoagglutinins because they are more likely to be of high titer and, in addition, pass across the placenta more readily; (5) cases of congenital hemolytic disease due to A-B-O sensitization are usually milder than cases due to Rh sensitization, and patients frequently recover without treatment, but severe or even fatal cases, with liver damage and kernicterus, also occur, and in these cases the A-B-O factors are the cause; (6) when Rh-negative individuals are exposed to Rh-positive blood of an incompatible blood group, the principle of competition of antigens may operate, so that the agglutinogens A or B may suppress the antigenicity of the Rh factor.

In the case of pregnancy in a union between an Rh-positive husband and an Rh-negative wife, one may expect the first-born baby to be free from symptoms. Physicians should be ready to proceed with the proper treatment of children of an Rh-positive father and an Rh-negative mother by exchange transfusion with Rh-negative blood.

A-B-O hemolytic disease, in contrast to that caused by the Rh factor, frequently affects the first-born infant.[162, 177-179]

Chapter 78

Other blood group systems

ADDINE G. ERSKINE

LEWIS BLOOD GROUPS AND TESTS FOR A-B-O SECRETORS—FACTORS Le^a AND Le^b

In 1946 Mourant[180] found in the serum of a blood donor an antibody that agglutinated the blood cells of 24 out of 96 random individuals belonging to group O. This antibody possessed properties of type-specific cold agglutinins in that the reaction with it was stronger at low temperatures than at body temperature. The blood factor detected by this serum was named **Lewis** (**Le**) after one of the donors whose serum contained the antibody. An identical antibody was found in 1948 in Denmark by Andresen,[181] who shortly thereafter found a second type of serum which gave almost antithetical reactions. The factor identified by Mourant's antiserum is called **Le**^{a}, whereas that which appears to be allelic is called **Le**^{b}. Many examples of the **Le**^{b} antibody have now been found, and most of these give good positive reactions only if the cells being tested are group O or group A_2.[182]

In 1948 Grubb[183] reported that practically all persons who have the **Le**^{a} factor on their red cells are nonsecretors of the A-B-O (H) blood group substances, whereas those lacking **Le**^{a} are almost always secretors. The words "secretors" and "nonsecretors" are used to refer to individuals who secrete the antigens **A**, **B**, and **O** (H). The Lewis substance is a mucopolysaccharide chemically indistinguishable by present methods of identification from A-B-O substances.[184, 185]

The A-B-O factors are not restricted to the red cells but are also present in the cells of tissues and organs with the exception of nerve tissue, epithelium, skin appendages, bone, and cartilage. The blood group substances present in red blood cells and tissue cells can be extracted with alcohol and other lipid solvents, but only in small amounts. Since the blood group substances also occur in water-soluble form, all persons can be divided into 2 groups, those who secrete the substance, called secretors, and those who do not, called nonsecretors. The blood group substances can be extracted with aqueous solutions from tissues and organs, especially salivary glands and gastric mucosa, of secretors, and these substances are present in high concentration in saliva, gastric juice, and semen. Water-soluble group substances are not demonstrable in the body fluids or secretions of the nonsecretors. It has been shown that the saliva of **Le**^{a}-positive individuals is capable of neutralizing anti-**Le**^{a} serum.

About 75-80% of Caucasoids are secretors. Approximately 80% of infants less than 3 mo. of age have the **Le**(**a**+) factor on their red cells (nonsecretors), but by the end of the first year of life this frequency drops to 20%, the adult level. Unger noted that all cord blood specimens which he examined were **Le**(**a**–). It has been found that the more the **Le**(**a**+) cells are washed with saline the less they are agglutinable by anti-**Le**^{a} serum, although Race and Sanger were not able to remove **Le**(**a**+) by washing. This observation might necessarily depend on the antiserum used in testing the cells.

According to Andresen,[186] 4 phenotypes are present in the Lewis system, which can be determined by 3 agglutinins—anti-**Le**^{a}, anti-**Le**^{b}, and one that has received the temporary name of anti-**X**:

Le(a+b–) are always nonsecretors.

Le(a–b+) are always secretors.

Le(a–b–) are always secretors when they give a positive reaction with anti-**X**. Such individuals are found only in group A_1.

Le(a–b–) which give negative reactions with anti-**X** are either secretors or nonsecretors.

In the case of the Lewis system, the phenotypes apply only to adults. Other rules apply to infants below the age of about 1 yr. **Le**^{b} is typically dominant in adults, and this property is faintly developed in infants. **Le(a+b+)** is very common among small children but has never been demonstrated in adults. Perhaps the use of more potent anti-**Le**^{a} serum in the future may reveal this type in adults also.

Transmission of **Le**^{a} parallels that of the secretor/nonsecretor trait. Two Le(a+) parents, both nonsecretors of the A-B-O substance, have all Le(a+) children, also nonsecretors. If both parents are Le(a–), the children may be Le(a+) as well as Le(a–); the Lewis factor behaves like a mendelian recessive.

The Lewis substance appears to be produced primarily in the tissues and body fluids and secondarily adsorbed onto the red cells.

When the red cells are tested with both anti-**Le**^{a} and anti-**Le**^{b} sera, conflicting results are obtained, perhaps because anti-**Le**^{b} sera give many more positive reactions with cells of groups O and A_2 than with cells of groups A_1 and B. When tests are confined to blood cells of groups O and A_2, **Le**^{a} and **Le**^{b} are almost, but not completely, antithetical. The presence of **Le**^{a} on the red cells is demonstrable only in homozygous individuals, genotype Le^aLe^a. This may represent a gene dosage effect (Wiener) since all available anti-**Le**^{a} sera to date have been of very low titer and avidity.

The **Lewis** factor is important in genetic and family studies and in medicolegal practice to determine secretors and nonsecretors of the A-B-O substance. The significance of the **Lewis** factor in blood transfusions is that natural or immune antibodies for all the blood factors may produce unexpected agglutinations, making it difficult to obtain compatible blood for transfusions. The primary purpose of testing for the **Le** factor, however, is to determine secretors and nonsecretors, important in medicolegal blood grouping serology, especially when blood group substances can be demonstrated in saliva on cigarette stubs or postage stamps, and in seminal stains in rape cases. The concentration of the blood group substances in such materials is relatively high, and the results of the tests are therefore usually clear-cut. The principle of these tests is to determine the capacity of saline extracts to inhibit specifically the reactions of anti-**A** and anti-**B** sera. This method has also been applied successfully to blood grouping of corpses when there was no blood available with which to carry out direct agglutination tests. In such cases saline extracts of muscle tissue are prepared and used for the test. Errors in **Lewis** testing are avoided by including suitable controls. Tests on tissues and secretions are restricted to the A-B-O groups.

Testing for Le^a

In testing for the **Le**^{a} blood factor, certain antisera require that the unknown cells be enzyme-treated, whereas other sera do not. If the anti-**Le**^{a} serum requires enzyme-treated cells, it will react with the cells both at 4° C. and at room temperature, but those sera that do not require enzyme-treated cells react only at refrigerator temperature.

1. Prepare cell suspensions according to the directions on p. 1463, wash twice, and resuspend to a 3-5% concentration. If the antiserum requires enzyme-treated cells, prepare ficinated cells according to the short method on p. 1463.
2. Place 1 drop of cell suspension of unknown blood in a small Kahn tube.
3. As a control place 1 drop of Le(a+) cells in a small Kahn tube and 1 drop of Le(a–) cells in another tube, both properly labeled.
4. Add 1 drop of anti-**Le**^{a} serum to each of the 3 tubes and mix thoroughly.
5. Place the tubes in a refrigerator at 4° C. for 1 hr. At the end of this period, read the results as positive if clumping has occurred or as negative if no clumping has taken place. Read the reactions in the control tubes and use these as comparisons in judging the results. Do not make antiglobulin (Coombs) tests when testing for the **Le**^{a} factor.

Considerable difficulty has been encountered in carrying out tests for the **Lewis** factor. Another test has been devised for determination of group substance O secretors and nonsecretors. The method makes use of a reagent prepared from a seed, *Ulex europaeus*. The reagent is called "anti-**H** Lectin" and is available commercially.* It is not specific for blood group O because the *Ulex* seed extract, like anti-O sera in general, tends to react most strongly not only with red cells from individuals of group O but also of subgroup A_2. Because of this characteristic, the serum is called anti-**H** and not anti-**O**.

---

*Certified Blood Donor Service, Inc., Jamaica, L. I., N. Y.

As previously stated, the A-B-O factors are not restricted to red blood cells, but in approximately 80% of adults they are also present in water-soluble form in body fluids and in such secretions as saliva, gastric juice, nasal secretion, semen, and amniotic fluid. Those who have these substances in their secretions are secretors and those who lack the substances are nonsecretors. Schiff and Sasaki have shown that the secretor trait is inherited by a pair of allelic genes, independent of the A-B-O groups. Individuals can be classified as secretors or nonsecretors by testing the saliva. The method of testing saliva is by the inhibitory method.

Inhibitory test of saliva, semen, and other body fluids for detection of A-B-O secretors

A-B-O secretors

In this test the blood group-specific substance of saliva is used to neutralize the anti-**A** or anti-**B** agglutinin of serum. If the anti-**A** agglutinin is inhibited, addition of group A cells will result in absence of agglutination. Similarly, if anti-**B** is inhibited, the antiserum will no longer agglutinate group B cells.

The agglutinin inhibitory test may be used for determining the blood group of semen, saliva, or other body fluids but may not be used for blood.

Since saliva contains enzymes that can destroy the A-B-O blood group substances, as soon as the specimen is collected it must be placed in a boiling water bath for 10 min. or brought to a boil over a Bunsen flame. Remove the coagulated mucus by centrifugation and transfer the supernatant opalescent fluid to a fresh test tube. The specimen so prepared must be kept refrigerated if not tested at once.

Three small Kahn tubes are used for each test. It is well to use saliva from known secretors and from known nonsecretors as controls during the test. The controls are treated in the same manner as the unknown specimens.

1. In **tube 1** place 1 drop of the treated saliva. Add 1 drop of anti-**A** serum.
2. In **tube 2** place 1 drop of the treated saliva. Add 1 drop of anti-**A** serum.
3. In **tube 3** place 1 drop of the treated saliva. Add 1 drop of anti-**B** serum.
4. Allow to stand at room temperature for 1 hr.
5. To tube 1 add 1 drop of saline-suspended group A_1 cells.
6. To tube 2 add 1 drop of saline-suspended group A_2 cells.
7. To tube 3 add 1 drop of saline-suspended group B cells.
8. Allow to remain in contact for 30 min. at room temperature, shaking the tubes every 5 min. Observe macroscopically for agglutination or lack of agglutination. Confirm the readings by placing a small amount of sediment from each tube on a properly labeled glass slide and examine under a microscope, or observe the contents of the tubes under a scanning lens.

If the results in tube 1 or 2 are negative, the saliva contained group-specific substance A and was derived from a secretor of A substance.

If the result in tube 3 is negative, the saliva contained group-specific substance B and was derived from a secretor.

Saliva from nonsecretors will not inhibit the action of anti-**A** on group A cells nor of anti-**B** on group B cells. See Table 333.

Explanation: Agglutinogens present in saliva (or semen, etc.) will absorb or inhibit their corresponding agglutinins from known sera. The A agglutinogen will inhibit anti-**A**, which leaves anti-**A** serum inactive against group A cells. The B agglutinogen will inhibit anti-**B**, leaving the anti-**B** serum inactive against group B cells.

Use of anti-H lectin to detect secretors of O and A_2 substances

The discovery that extracts of seeds of *Ulex europaeus* gave agglutination reactions resembling those of anti-**O** serum has made

Table 333. *Results possible in inhibitory test for secretors*

+	+		Nonsecretor of A substance
		−	Secretor of B substance
		+	Nonsecretor of B substance

available a practicable method of testing for the secretor character.[187, 188] This reagent gives sharp reactions despite its low titer and can be used for testing saliva of individuals of any A-B-O group. It is not specific for blood group O since it tends to react most strongly not only with red cells from group O individuals but also with red cells from group A_2 persons. It is therefore called anti-**H** and not anti-**O**. (See pp. 1543 and 1620.)

Collect the saliva in dry, wide-mouthed test tubes. The individual being tested may chew on gum or paraffin to increase the flow of saliva. In drooling infants or in young babies the saliva can be scooped up into small test tubes. It may be necessary to collect the saliva from infants on cotton swabs by rubbing the swabs across the floor of the mouth and inside the cheeks until they are saturated. Then force the swabs into a small tube to express the saliva. Repeat the process until an adequate quantity is obtained.

As soon as the specimens are collected, place in a boiling water bath for 10 min. or bring to a boil over a Bunsen burner. Centrifuge the coagulated mass and transfer the supernatant opalescent fluid to a fresh test tube. Store in a refrigerator until ready to use.

Best results are obtained when the tests are made in serial dilutions. Prepare a 4-fold series of dilutions of the heated saliva as follows: undiluted, 1:4, 1:16, 1:64, and 1:256. (Method of preparing accurate dilutions is explained on p. 1476.)

1. Prepare 5 small Kahn tubes, inside diameter 7-8 mm., for each specimen and for (a) a specimen from a known secretor and (b) a specimen from a known nonsecretor.
2. Place 1 drop of saliva in its corresponding tube in the series (1 drop of undiluted specimen in tube 1, 1 drop of 1:4 in tube 2, etc.).
3. Add 1 drop of anti-**H** reagent to each tube.
4. Mix and allow to stand for 5 min. at room temperature.
5. Add to each tube in each series 1 drop of 2% suspension in saline of fresh, washed group O cells.
6. Shake the rack and place in a refrigerator for 2 hr. When the rack is removed from the refrigerator, place it on a tray of ice to keep the tubes cold while reading the results of the test. If no positive control saliva is available, use one of the commercial preparations of A-B blood group substance.

If the individual is a secretor of the H substance (O and A_2), the group O cells will not be agglutinated. If the individual is a

nonsecretor, the cells will be agglutinated. Refer to Tables 334 and 335.

Recapitulation on Lewis blood groups

It has been known for some time that occasionally human sera contain naturally weak agglutinins that give reactions unrelated to the A-B-O system. Many of these remain unclassified. In view of the poor reactions given by these weak irregular agglutinins, which give the strongest clumping at low temperatures under conditions in which nonspecific cold agglutinins interfere, there was little interest in the natural irregular agglutinins until the **Lewis** factors were found. Two related **Lewis** factors have been found and are designated as **Le**^{a} and **Le**^{b}. It has been established that adults who are Le(a+) are almost invariably nonsecretors of the A-B-O substances, whereas Le(a–) persons are secretors. Many aspects of the **Lewis** blood factors, especially the relationship between **Le**^{a} and **Le**^{b}, are still unclear because of the difficulty of obtaining potent specific reagents. Although considerable difficulty has been encountered in carrying out tests for the **Lewis** factor, 3 well-defined Lewis types have been identified: Le(a+b–), Le(a–b+), and the rare Le(a–b–). In contrast to all other known blood factors, the **Le**^{a} factor appears to be hereditarily transmitted by a simple mendelian recessive.

Wiener has suggested that the **Le**^{a} substance is identical with the **T** substance found in nonsecretor saliva by Uyeyama and that **Le**^{b} substance is the same as or related to the **H** substance of secretor saliva, although some preparations of **H** substance have **Le**^{b} activity whereas others do not.

Division of human beings into 2 hereditary types,[189] depending on the presence or absence of blood group substances in the secretions and body fluids, is determined by identification of the **Le** factor. Those who are Le(a+) are nonsecretors, and those who are Le(a–) are secretors. For example, in group A individuals who are secretors, the blood group substance A is demonstrable in high concentration in the saliva and other secretions, whereas in nonsecretors of group A no blood group substance A is demonstrable. It has been suggested that the reason why most babies of group A or group B do not have erythroblastosis fetalis when their mothers are group O is that the babies are secretors, so that the maternal isoantibodies that reach their circulation are neutralized before they can combine with the baby's erythrocytes, and that only nonsecretors are affected. However, since the same high incidence of secretors has been found among babies with erythroblastosis fetalis as in the general population, this cannot be the correct explanation. A more plausible explanation is the incomplete development of the A-B-O agglutinogens in the newborn infant and the low avidity of the agglutination reactions of their red cells.

FACTORS P AND Tj^{a}—P-p SYSTEM

Landsteiner and Levine[190] in 1928 described an agglutinogen P in human blood, more frequently found in Negroes than in whites. They demonstrated this factor with immune rabbit serum. Occasionally a natural irregular anti-**P** agglutinin is found in human serum, which acts on the P agglutinogen in human cells. The reaction is extremely weak but may sometimes be demonstrated if the test is made in small tubes and not centrifuged but kept in a water bath at 20° C., shaken occasionally, and then examined under the microscope.

Anti-**P** agglutinins have been found in the sera of certain normal, nonimmune animals, such as rabbits, hogs, cats, and cattle. Factor **Q** of the Japanese investigators has proved to be the same as factor **P**.

Landsteiner and Levine concluded that the property P is not a single, well-defined entity but a group of related agglutinogens.

Occasionally anti-**P** agglutinins are found in normal human sera and are of sufficiently high titer to be usable as diagnostic reagents. Anti-**P** sera have been prepared from selected sera from P-negative professional donors containing an exceptionally high titer of natural anti-**P** agglutinins.

Tests for P agglutinogens are at times helpful in special problems of incompatibility in blood transfusions. The tests have also been used in anthropologic investigations and in serologic studies on individual differences in human blood.

The P agglutinogen is inherited as a simple mendelian dominant by a pair of allelic genes designated *P* and *p*, respectively. The tests can therefore be used as an additional factor in medicolegal cases of disputed parentage.

The names "type P" and "type pp" are used instead of the terms P positive and P negative.

There are also bloods containing a variant of the P agglutinogen.

Genotypes of P are *PP* and *Pp*; genotypes of pp are *pp*. Approximately 79% of Caucasoids and 98% of Negroids have been found to belong to type P, whereas 25% of Caucasoids and only 2% of Negroids have been found to belong to type pp. The percentage of type P among Mexican Indians has been found to be 78.9 and among Japanese, 30.

Most anti-**P** sera have the property of cold agglutinins for all human red cells. Removing the nonspecific antibodies by absorption weakens the anti-**P** agglutinins, making it difficult to prepare a serum to test for factor **P**.

Another type other than P positive and P negative was found by identifying an antibody in the serum of a blood donor. The factor detected by this serum was named **Jay** or **Tj**^{a} after the donor, Mrs. Jay. The anti-**Tj**^{a} serum agglutinated the red cells of 3000 consecutive random group O individuals but did not react with the red cells of the donor (Jay). Individuals who lack this factor are rare.

Factor **Tj**^{a} has been found to be related to **P**.

In the P system the following agglutinogens and their corresponding factors are found: P_1, containing factors **P** and **Tj**^{a}; P_2, with factor **Tj**^{a} only; and p, with no factors of this system.

Tests for factor P—Wiener–Unger

1. Prepare a saline suspension of the cells to be tested, wash once in saline, and resuspend to 3-5% concentration without enzyme treatment.
2. Place 1 drop of these cells in a small Kahn tube (7 mm. inside diameter).
3. Add 1 drop of anti-**P** serum.
4. Mix thoroughly and place in a refrigerator at 4° C. for 2 hr. Tilt the tube gently to dislodge the sediment and read the reactions macroscopically and under a scanning lens. Take care not to let the tube warm during the reading. Keep the rack containing the tubes in ice water or on a tray of ice until the readings have been made.

If the cells have agglutinated, they contain the **P** factor. If they fail to agglutinate, they do not contain the **P** factor. Do not make an antiglobulin test on cells when examining for the **P** factor.

See Table 336 for possible results.

Table 336. *Results possible in tests for factor* **P***

Unknown cells + *anti-***P** *serum*	*Phenotype*	*Genotype*
+	P	*PP* and *Pp*
−	pp	*pp*

*After A. S. Wiener, Brooklyn, N. Y.

Positive and negative control bloods should be included in the test, and the reactions in these tubes should be used for comparative reading of the unknown bloods.

Since the antibody is a cold agglutinin, the reactions will reverse if the tubes warm to room temperature. The proper temperature must be maintained throughout the test to avoid incorrect results. On humid days moisture sometimes condenses on the tubes. This moisture must be wiped off before the readings can be taken.

K-k SYSTEM—KELL-CELLANO TYPES

In 1946 Coombs et al.[191] found an antibody in the serum of a mother of an erythroblastotic infant which gave reactions unrelated to the Rh-Hr blood system. The factor defined by this antibody has been found in 7%[191] to 12.9%[192] of all persons tested. The blood factor was named **Kell**, after the patient from whom the serum was obtained. The factor **Si** in the serum of a patient who had had a hemolytic transfusion reaction described in 1947 by Wiener and Sonn-Gordon[192] proved to be identical to the **Kell** factor. In order to avoid confusion Wiener discarded the symbol **Si** for this blood factor which he had independently discovered and adopted the symbol **K** used by the British investigators.

Levine et al.[193] found a serum giving reciprocal reactions to anti-**K** in the serum of a mother of a mildly erythroblastotic infant. The antibody was called anti-**k** and the factor it defined, **k**. Additional examples of anti-**k** were found by Wiener and other investigators. The antibody found by Levine was derived from a patient named Cellano, and factor **k** is at times referred to as the **Cellano** factor. It has an incidence of 99.8% among Caucasoids.

When tests are made with both anti-**K** and anti-**k** sera, 3 types can be differentiated: type KK in 0.25%, type Kk in 9.5%, and type kk in 90.25% of Caucasoids.

Most of the anti-**K** sera must be used with the conglutination and antiglobulin technics. Limited quantities of anti-**K** serum are available commercially.

Testing for K factor—Wiener

Plasma conglutination method

Have on hand fresh oxalated plasma, either of group AB (no anti-**A** or anti-**B** agglutinins) or of a blood group compatible with the blood being tested. This is the supernatant liquid from whole blood taken in 3:2 dry oxalate (pp. 1462 and 1463).

1. Make a saline suspension of cells to be tested and wash once with saline; then resuspend to a 2% concentration.
2. Place 1 drop of washed saline-suspended unknown cells in a small tube (7-8 mm. inside diameter).
3. Add 1 drop of anti-**K** serum.
4. Mix and place in a water bath at 37° C. for 1 hr.
5. Remove the supernatant fluid with a fine capillary dropper **as completely as possible.**
6. Add 1 large drop of oxalated (AB) plasma and resuspend the sediment in it.
7. Place in a water bath at 37° C. for 1 hr.
8. Shake gently to dislodge the sedimented cells and read the reaction macroscopically and under a scanning lens.

If the cells have agglutinated, they are **K** positive. If they have not agglutinated, they are **K** negative.

Antiglobulin technic

1. Make a saline suspension of cells to be tested, wash once in saline, and resuspend in enough saline to make a 3% concentration.
2. Place 1 drop of this suspension in a small (7 mm. inside diameter) tube.
3. Add 1 drop of anti-**K** serum and mix.
4. Place in a water bath at 37° C. for 30-60 min.
5. Wash the mixture rapidly with saline 3 times, that is, fill the tube with saline, centrifuge, and decant the supernatant fluid; repeat 3 times. Remove and discard all the supernatant saline after the last washing, leaving only 1 drop.
6. Add 1 drop of antiglobulin (Coombs) serum and shake.
7. Centrifuge at low speed, 500 r.p.m., for 1 min.
8. Gently dislodge the sediment and read macroscopically and under a scanning lens.

If the cells have agglutinated, they contain factor **K**, but if they have not agglutinated, factor **K** is not present.

Testing for k factor

Since the anti-**k** serum contains a univalent antibody, best results are obtained by use of the antiglobulin technic.

1. Prepare a fresh suspension of the cells to be tested, wash once, and resuspend in saline to a 3% concentration.
2. Place 1 drop of the cell suspension in a small (7 mm. inside diameter) tube.
3. Add 1 drop of anti-**k** serum.
4. Mix and place in a water bath at 37° C. for 60 min.
5. Wash rapidly 3 times with saline (see above) and decant the saline after the last washing, leaving the cells suspended in 1 drop of the last saline.
6. Add 1 drop of antiglobulin (Coombs) serum and mix.
7. Centrifuge at 500 r.p.m. for 1 min.
8. Gently dislodge the sediment and read macroscopically and under a scanning lens.

Include as controls specimens of blood of known types KK, Kk, and kk with each test.

If the unknown cells have agglutinated, they contain factor **k**. If they have not agglutinated, they do not contain factor **k**. Refer to Table 337.

Factors Kp^a and Kp^b (Penney factor)

After the **K-k** factors had been found another antibody was discovered in the serum of an individual who had never been exposed to the antigen either through pregnancy or through transfusion. Two more sera of identical specificity were found later. The new factor determined by the antiserum was named **Penney** and it was later determined that it is related to the K-k system. This discovery gave rise to the identification of 2 factors, now designated as **Kp**^{a} and **Kp**^{b}.

Factor Ku

In 1961 Corcoran et al.[194] reported finding a new antibody, anti-**Ku** (anti-**Peltz**) in the Kell blood group system. Two unrelated families have been reported in which the Kell phenotype K negative, k negative, Kp^a negative, and Kp^b negative occurred.[195, 196] The propositus of the first family had in her serum antibodies that caused hemolytic disease in her fetus. Her serum has been found to contain an antibody which apparently is a new antibody in the Kell system, and it has been designated anti-**Ku**. It seems to detect an antigenic factor in the Kell system of nearly universal occurrence in human red cells. Successive adsorptions and elutions were performed using 3 bloods selected in such a way that the final eluate could contain no previously known blood group antibody. It agglutinated all of 525 bloods chosen at random and failed to agglutinate only very rare bloods which were of highly unusual Kell types. The letter "u" was selected because of the almost universal occurrence of the antigenic factor in human red cells.

Importance of K-k factors

Factors **K** and **k** are far less antigenic than is the **Rh$_0$** factor. As a cause of erythroblastosis fetalis, factor **K** ranks with factor **hr′** in importance. Tests for detecting the antibodies are very delicate and must be carried out with the greatest of care.

Anti-rh^w + K*

Serum anti-**rh^w+K** contains antibodies which detect the 2 blood factors **rh^w** and **K**. When this reagent is used for testing blood cells, it serves as a screening test for both factors. Both factors **rh^w** and **K** are of low frequency in the general population, and a great majority of bloods lack both. Such bloods are quickly identified by their negative reactions with this antiserum. Only the small percentage of positively reacting bloods need be further tested to determine whether they contain factor **rh^w** or **K** or both.

The tests are carried out by the saline agglutination and antiglobulin technics. A negative test therefore demonstrates that the unknown cells are not coated by antibodies, and this takes the place of the direct antiglobulin (Coombs) test.

If the reaction is positive, however, the unknown cells may already have been coated before this test was made. In such cases a direct antiglobulin test should be made of the cells. If such test is positive, it is usually not possible to determine whether or not factor **K** is present on the cells.

The **rh^w** antibodies in the anti-**rh^w+K** serum will clump cells containing the **rh^w** factor in saline suspension, whereas the **K** antibody reacts only by the conglutination and antiglobulin technics. The antiglobulin technic, which detects the **K** factor, also serves to improve the reactions for factor **rh^w**, and this test will also be positive, as previously stated, if the cells are coated by antibodies.

The method is of limited value when testing blood from patients known to have acquired hemolytic anemia or erythroblastosis fetalis because in such patients the cells are coated with antibodies and therefore give a positive direct Coombs reaction.

Procedure:

1. Prepare a cell suspension in saline, wash once, and resuspend the cells to a 2 or 3% concentration in saline.
2. Place 1 drop of the cell suspension in a tube (7 mm. inside diameter).
3. Add 1 drop of anti-**rh^w+K** serum.
4. Mix and place for 1 hr. in a water bath at 37° C.
5. Gently dislodge the sediment and read the reactions macroscopically and under a scanning lens.
6. Centrifuge at 500 r.p.m. for 1 min. and read again.

Clumping is a positive reaction and lack of clumping is a negative reaction.

Test all negatively reacting bloods by the antiglobulin technic:

1. Wash the sediment 3 times with large volumes of saline (fill the tube to the top with saline and mix the cells with the diluent, centrifuge, decant, and repeat 3 times).
2. After the last washing remove all but 1 drop of saline and resuspend the cells in this drop.
3. Add 1 drop of antiglobulin (Coombs) serum.
4. Centrifuge for 1 min. at 500 r.p.m.
5. Gently dislodge the sediment and read. See Table 338.

The vast majority of bloods will react negatively in both the saline agglutination and the antiglobulin methods. Such bloods lack both factors **rh^w** and **K**, and at the same time the negative reactions in the second stage of the test show that the unknown cells are not coated by antibodies.

If the reactions are negative in the first stage of the test but positive in the second stage, this indicates absence of the **rh^w** factor and the probable presence of the **K** factor. If the direct antiglobulin test is negative and tests with pure anti-**K** serum are positive, the presence of **K** is confirmed. If, on the other hand, the direct antiglobulin test is positive, it is generally not possible to determine presence or absence of factor **K** with any degree of reliability.

If the reactions are positive in the first stage of the test, they will also be positive in the second stage, demonstrating the presence of the **rh^w** factor. This can be confirmed, if required, by tests with pure anti-**rh^w** serum.

Since factors **rh^w** and **K** are inherited as simple mendelian dominants, theoretically this test could be used occasionally in cases of disputed paternity, but the number of investigations already carried out on blood factors **rh^w** and **K** is limited and the reagents available are of only moderate titer. The application of these tests in medicolegal cases, there-

F-f SYSTEM—DUFFY OR F FACTORS

In February, 1950, Cutbush et al.[201, 202] and van Loghem and van der Hart[203] independently reported the discovery of a new blood factor. This new factor was not part of the A-B-O, M-N, P, or Rh-Hr systems or of other previously described systems. The antibody was found in the blood serum of a hemophiliac who had had a long series of blood transfusions over a period of 20 yr. and who sustained a mild transfusion reaction after the last injection of blood. Since this patient's name was Duffy, the antibody was designated anti-**Duffy**, and the factor it identified was called the **Duffy** factor. Other examples of **Duffy** sensitization were later reported by Ikin et al.,[204] Rosenfield et al.,[205] and Wiener.[206]

The **Duffy** factor is important in hemolytic transfusion reactions when **Duffy**-positive blood is transfused into **Duffy**-negative patients and in some of the puzzling cases of erythroblastosis fetalis not caused by other factors.

The symbol **Fy** was introduced by Cutbush and Mollison to indicate the **Duffy** factor. Those with the factor were originally called Fy(a+) and those who lacked the factor, Fy(a−). It was later found that the **Duffy** factor is inherited as a simple mendelian dominant by a pair of allelic genes, designated Fy^{a} and Fy^{b}. More recently Wiener has shortened the symbols to **F** and **f** for the factors and *F* and *f* for the genes.

All anti-**F** sera so far produced have been usable only by the antiglobulin method.[207] When the red cells are already coated with antibody, as in autohemolytic anemia or erythroblastosis fetalis, tests for the **F-f** factors cannot be carried out reliably. The tests are not made routinely in the usual hospital laboratory since identification of the factor is difficult. With the production of more reliable anti-**F** serum these tests no doubt will be added to the hospital routine.

Determining F-f factors

1. Make a suspension of the cells in saline, wash once in the usual manner, and resuspend to a 3% concentration in saline.
2. Place 1 drop of the 3% suspension of cells in a small tube (7 mm. inside diameter).
3. Add 1 drop of anti-**F** (**Fy**^{a}) serum.
4. Mix and place in a water bath at 37° C. for 30-60 min.
5. Wash rapidly with saline 3 times. Leave 1 drop of saline on the cells after the last washing. Resuspend the cells in this drop of saline.
6. Add 1 drop of antiglobulin serum (Coombs) and mix.
7. Centrifuge at 500 r.p.m. for 1 min.
8. Gently dislodge the sediment and read macroscopically and under a scanning lens.

Always include positive and negative controls. The washing with saline must be carried out rapidly to prevent elution of the antibody from the cells, with resulting false negative reactions. In addition, the red cells are fragile and may undergo

Table 339. *Results possible in F-f tests*

spontaneous clumping or hemolysis if kept in saline suspension for too long a time, another reason for washing rapidly.

M-N-S-U SYSTEM

Agglutinogens M and N

In 1927 Landsteiner and Levine[190, 208] discovered the M and N types when they immunized rabbits with human red blood cells. When the antisera thus produced by the rabbits were absorbed with certain samples of human blood, they still contained agglutinins acting on the majority of bloods of all 4 groups, although some of the bloods were not agglutinated. The antibodies produced by the rabbits were designated as anti-**M** and anti-**N**, respectively, and the factors they identified as **M** and **N**. The immune rabbit sera could not be used directly because they contained antibodies reactive for all human cells and therefore had first to be diluted and absorbed with human cells lacking the blood factor in question. The original method of immunizing rabbits is still used at the present time.

The anti-**M** and anti-**N** reagents define 3 types of human blood—M, N, and MN—with approximate frequencies among Caucasoids of 30%, 20%, and 50%, respectively. Type M contains agglutinogen M; type N, only agglutinogen N; and type MN, both agglutinogens M and N.

It has been proved by family studies that the 3 M-N types are transmitted by a pair of allelic genes, designated *M* and *N*, respectively. There are thus 3 genotypes corresponding to the 3 phenotypes: type M, genotype *MM*; type N, genotype *NN*; type MN, genotype *MN*. Because of the clear-cut heredity of the M-N types, the M-N tests find frequent application in medicolegal cases of disputed parentage and are also helpful in twin studies to determine whether a pair of twins of the same sex are monozygous or dizygous.

Agglutinogens M and N are but weakly antigenic in man and are ordinarily disregarded when selecting donors for blood transfusion. They are not as important as the A-B-O and Rh-Hr types for clinical medicine, but nevertheless anti-**M** and anti-**N** do occasionally occur in human sera, and when they do, they can give rise to hemolytic transfusion reactions. If present in the serum of a pregnant woman, this can lead to hemolytic disease in her newborn baby.

Wiener has noted that in the majority of transfusions donor and recipient belong to different M-N types, and the **M** and **N** factors are then useful as natural tags to trace the fate of the donor's cells in the patient's circulation. Such survival tests (designated "differential agglutination" by Wiener) are helpful in the study of transfusion reactions and in comparing the relative merits of different methods of storing blood in blood banks.

Only rarely have human sera been found to contain natural anti-**M** agglutinins, and natural anti-**N** is found even less frequently in human beings.* Although some cases of isoimmunization to factor **M** have been reported, the **M** and **N** factors are most important medicolegally in cases of disputed paternity. It is generally considered that agglutinogens M and N can be disregarded when selecting donors for blood transfusion therapy, but if a patient requires multiple transfusions over a period of months or years, the possibility of isosensitization to the M agglutinogen must be seriously considered.[209]

Bloods lacking both agglutinogens have not been found in tests on many millions of blood specimens, although variants and subtypes have been demonstrated.

Wiener and Forer[210] reported a case of **M** sensitization in an individual of type N in 1941, and Broman reported another case in 1944.[211] In 1948 Wiener et al.[212] indicated that sensitivity to agglutinogen M could be an important source of hemolytic reactions for type N individuals who received a series of blood transfusions when type M blood was injected. In 1950 Wiener[213] described a hemolytic transfusion reaction due to sensitization to the **M** factor in a type N patient.

It is interesting to note that whereas the **M** and **N** factors are seldom antigenic to man, they are highly antigenic to rabbits.

Factors and subtypes of agglutinogen M

(1) **$\mathbf{M_i}$, $\mathbf{M_{ii}}$, $\mathbf{M_{iii}}$, $\mathbf{M_{iv}}$, etc.:** As Wiener has pointed out,[214] not all anti-**M** agglutinins are identical in specificity, showing that there are more than one kind of **M** factor. If the agglutinin which reacts with human red cells but not with blood from chimpanzees or monkeys is designated as anti-$\mathbf{M_i}$, that which detects a factor common to both human M blood and chimpanzee blood but absent from the blood of the lower primates as anti-$\mathbf{M_{ii}}$, etc., then human M agglutinogen has all of the blood factors $\mathbf{M_i}$, $\mathbf{M_{ii}}$, $\mathbf{M_{iii}}$, $\mathbf{M_{iv}}$, etc., chimpanzee blood has factors $\mathbf{M_{ii}}$ and $\mathbf{M_{iii}}$, etc.

---

*A report by Masters and Vas[208a] discusses anti-**N** formed by a 10-week-old infant.

The discovery of the Rh factor came about when Landsteiner and Wiener prepared anti-**M** reagents by injecting the blood of rhesus monkeys into rabbits for the purpose of producing anti-**M** reagents which might be specific for human M cells.

(2) **Subtype $\mathbf{M_2}$:** Friedenreich and Lauridsen[215] reported a weak form of the **M** factor which differs qualitatively from ordinary **M**. Red cells carrying the antigen were agglutinated by 5 out of 9 rabbit anti-**M** sera and by 1 out of 4 human anti-**M** sera.

(3) **Factor $\mathbf{M^c}$:** Dunsford et al.[216] described an antigen, called by them $\mathbf{M^c}$, which reacted with 25 out of 27 anti-**M** and with 5 out of 28 anti-**N** sera; they gave it the designation $\mathbf{M^c}$. The antigen has been found in only one family. It is considered to be intermediate between **M** and **N**.

(4) **Factor $\mathbf{M^g}$:** Allen et al.[217] found a very rare antigen, which they called $\mathbf{M^g}$, in one selected family. The antibody, anti-$\mathbf{M^g}$, has been found in 4 out of 500 normal people tested. It reacts with cells suspended in saline, and the reaction is rendered easier to read if the mixture of cells and serum are incubated for 5 min. at 37° C. and then centrifuged.

The gene for antigen $\mathbf{M^g}$ appears to be allelic to genes *M* and *N*. Blood determined by the genotype M^gM, if tested only with anti-**M** and anti-**N** sera, gives the reaction of type M blood. Blood representing genotype M^gN, tested only with anti-**M** and anti-**N** sera, appears to be N.

(5) **Factors $\mathbf{Mi^a}$ and Vw:** Levine et al.[218] found an antibody as the cause of hemolytic disease in the husband and 2 of the children of the propositus but not in 425 random group O and group A Caucasoids tested. They called the antibody anti-$\mathbf{Mi^a}$ and the factor it identified, $\mathbf{Mi^a}$.

Later, van der Hart et al.[219] described an antibody, anti-**Vw**, coating the cells of a baby. The direct antiglobulin test was positive. It was believed at first that **Vw** and $\mathbf{Mi^a}$ were identical, but later it was found that half the $\mathbf{Mi^a}$-positive persons were **Vw** positive and half were **Vw** negative. No $\mathbf{Mi^a}$-negative **Vw**-positive person has been found to date.

These 2 factors have been found to be related to the M-N-S-U system.

(6) **Factor $\mathbf{M^e}$:** Wiener and Rosenfield[220] in 1961 observed a discrepancy in the reactions obtained when using 2 different anti-**M** reagents to test the blood cells of a Negro involved in a medicolegal case of disputed parentage. Both reagents had been prepared in the usual manner by injecting rabbits with type M cells and absorbing the diluted serum with type N cells until they no longer agglutinated the absorbing cells (p. 1555). Further tests showed that the blood cells which gave the conflicting reactions had come from a type N individual who was He (Henshaw) positive (p. 1554), although the immunized rabbits had almost surely not received He-positive cells in error. These findings were similar to those of Mourant and associates which led to the discovery of the **He** antigen.

The anti-**M** reagent had been believed to be ordinary anti-**M** serum until the individual of type N.He was encountered. Five additional unrelated type N.He bloods were also agglutinated by this antiserum, but all other bloods of type N which were Henshaw negative, even if Hu (Hunter) positive, were not agglutinated.

When this anti-**M** fluid was absorbed with type M cells, it lost all its agglutinating activity, including that for type N.He (type N, He positive) red cells. Absorption with an equal amount of type N.He cells removed the reactivity for the absorbing cells but did leave some weak residual activity for cells having the **M** antigen, which could be removed by additional absorption with N.He cells. Thus this anti-**M** reagent presumably contained a single antibody for a blood factor shared by cells having the antigen **M** and cells of type N.He. Wiener and Rosenfield proposed the designation of this blood factor as $\mathbf{M^e}$ and the corresponding antibody as anti-$\mathbf{M^e}$.

The blood factor $\mathbf{M^e}$ appears to be shared by the **N** and **He** antigens and may be a source of error in M-N tests. If the putative father and the child in a case of disputed paternity are both type N, He positive, and the mother's type is N, He negative, a false exclusion of paternity can result if the individuals involved are tested at different times with different reagents. Thus, if the putative father is tested with ordinary anti-**M** and the child with anti-$\mathbf{M^e}$, the types of the 2 putative parents would be reported as N and that of the child as MN, with a resulting false exclusion of paternity.

Factors and subtypes of agglutinogen N

(1) $\mathbf{N_i}$ **and** $\mathbf{N_{ii}}$**, etc.:** As Wiener has shown, agglutinogen N also has a mosaic structure, just as M has.[221] Only 2 factors have been demonstrated so far—$\mathbf{N_i}$, which is peculiar to

human N cells alone, and $\mathbf{N_{ii}}$, which is shared by human N cells and chimpanzee red cells. When a human being inherits an M or N agglutinogen, this carries with it all of the serologic factors that characterize each agglutinogen.

(2) **Subtype N_2**: In 1935 Crome described a subtype of type N called N_2.[222] This type of blood is characterized by its very weak reactivity with anti-N sera. With many anti-**N** reagents, clumping may fail to occur at all or may be so weak as to be overlooked. In medicolegal cases this may lead to serious errors. It is always good practice to check all N-negative bloods with more than one anti-**N** serum of different lot numbers and from different manufacturing sources to prevent errors that might arise in this subtype.

Serology of M-N blood types

In parallel tests different anti-**M** and anti-**N** reagents generally give identical results with human red cells, but when the blood of lower primates is tested, the reagents often give different results, showing that these reagents possess different serologic specificities. There are at least 5 different **M** factors and at least 2 different **N** factors, as just explained. Since all human bloods with M agglutinogen have all the **M** factors and all N bloods have all the **N** factors, this can be disregarded when testing human blood because all anti-**M** and anti-**N** reagents necessarily will give the same results. An exception to this rule is the recently discovered anti-$\mathbf{M}^e$ (p. 1551), which gives strong reactions with blood from the rare type N individuals (most often Negroes) who have the **He** factor. Obviously, the unwitting use of anti-$\mathbf{M}^e$ reagents instead of standard anti-**M** can lead to the erroneous classification of such type N persons as type MN.

Ottensooser made the remarkable demonstration that extracts of seeds of *Vicia graminae* give reactions paralleling anti-**N** in specificity. Such seed extracts make excellent anti-**N** reagents but have not found wide practical application to date because of their limited availability.

Although it is possible to prepare anti-**M** reagents of very high titer, up to 256 units or higher, specific anti-**N** reagents, even though of excellent avidity, seldom exceed a titer of 10 units. The reason is that type M blood, in addition to the **M** factors, also has a weakly reacting **N**-like blood factor. For this reason, when anti-**N** immune rabbit serum is absorbed by type M blood to remove the species agglutinins, the desired anti-**N** agglutinin is weakened at the same time, whereas underabsorption will result in a nonspecific reagent. This applies to anti-**N** reagents prepared from *V. graminae* seeds as well as to anti-N rabbit or human serum. The presence of **N**-like factors in human type M cells explains why anti-**N** occurs so very rarely in human serum. Anti-**M** occurs less rarely; Wiener, for example, has observed more than a score of human sera with anti-**M** but has observed only a single human serum with anti-**N**. See footnote, p. 1550.

The M-N system, which at first was believed to be a simple system of only 3 types, has now become almost as complex as the Rh-Hr system. This has been due to the discoveries of such factors as **S, s, U, He, Hu, Vw, Mi,** $\mathbf{M}^g$, and $\mathbf{M}^e$.

Factors S and s of M-N-S-U system

Sanger et al.[223] in 1947 found in the serum of a mother of an erythroblastotic baby a blood group antibody that gave reactions different from any previously described.[224] The patient had been isosensitized to the $\mathbf{Rh_o}$ factor and also had $\mathbf{Rh_o}$ antibodies in the serum. Sanger and Race[223] were able to show the relationship between the factor detected by this antibody and the M and N agglutinogens. The factor determined by this antibody was designated **S** by Sanger and Race.

When persons of types M, MN, and N were subdivided according to their reactions with anti-**S** serum, 6 types of blood could be distinguished. The presence of **S** was noted by the use of the large letter "S" and its absence by the small letter "s." The 6 types are M.S, M.s, N.S, N.s, MN.S, and MN.s. The incidence of the **S** factor is not the same in the 3 M-N types, for whereas ⅔ of type M individuals are S positive, only about ⅓ of type N individuals are S positive.

When **S** is considered alone, 2 types are distinguishable, S+ and S–. S+ has a frequency of 56.1% and S– has a frequency of 43.9% in tests made on 394 donors in New York City and cited by Wiener.[214]

In 1951 Levine[225] found a serum of a mother of an erythroblastotic infant which gave reactions reciprocally related to anti-**S** and corresponding to those expected for factor **s**. Additional examples of this antiserum were subsequently found by other workers. Although a number of satisfactory anti-**S** sera have been found, sera of specificity anti-s are in very short supply and are more or less of a serologic curiosity.

To date there are 9 phenotypes recognized in the M-N-S system. This does not consider the factor **U** or any of the other factors to be discussed in the following pages. These 9 phenotypes are M.SS, M.Ss, M.ss, N.SS, N.Ss, N.ss, MN.SS, MN.Ss, and MN.ss. The factor **S** is a simple mendelian dominant. When factor **S** is associated with blood factor **M** in a parent, it is similarly associated in his children and in other members of his family. This is also true of factor **S** when it is associated with factor **N.** Factors **S** and **M** are not properties of different substances but are properties of one and the same agglutinogen, which supports the theory advanced by Wiener of multiple alleles in preference to that of linked genes.

Blood factor U

In 1953 Wiener et al.[226] found in the serum of a Negroid woman an abnormal antibody which strongly agglutinated the cells of the 2 donors whose blood had been used in transfusing her. Both of the donors belonged to group B MN rh kk, whereas the patient was group B MN $\mathfrak{R}h_1$rh kk. The patient had received Rh-negative blood because she had been erroneously typed as Rh negative, but this error in typing had no bearing on the hemolytic transfusion reaction reported by these authors.

This was a case of a fatal hemolytic reaction in a woman who entered the hospital with a diagnosis of bleeding peptic ulcer. She was given a transfusion, but this was discontinued after 100 ml. blood had been administered because of a reaction consisting of chills and fever. Another blood transfusion was carried out a week later. The patient died shortly thereafter.

The antibody found in the serum was of high titer and avidity. At body temperature the titer was approximately 400 units, and at refrigerator temperature it was only 40 units. This antibody was active by ordinary agglutination method in saline medium, and in this case it was a bivalent antibody. The strength of the reaction was not affected by proteolytic enzymes. In the original series of tests on 690 Caucasoids and 425 Negroids, no negative reactions with this serum were found among the Caucasoids, and only 4 negatively reacting persons were encountered among the Negroids. The factor detected by this patient's serum was called **U** to designate its almost universal nature.

In a further series of tests[227] of 1100 Caucasoids and 989 Negroids, no Caucasoids were found lacking factor **U**, and only 12 Negroids lacked the factor. Wiener et al.[227] showed the possible relationship of factor **U** to the M-N system. From family studies in the rare individuals of type uu (those who lack the factor), it was postulated that the factor is inherited by a pair of allelic genes *U* and *u*, *U* determining presence of the factor and *u*, its absence.

Although Wiener et al. showed that all U-negative individuals tested by them were either type N or type MN, Sanger et al.[228] found that all blood specimens that were **U** negative also lacked both blood factors **S** and **s**. Since it had previously been shown that factors **S** and s and blood factors **M** and **N** are associated with one another, this proved that blood factor **U** belongs in the M-N-S system.

In a series of tests on another sensitized patient, Wiener and Unger demonstrated that the **U** antibodies failed to clump saline-suspended ficinated cells, pointing to a relationship to the M-N-S system, because **M, N,** and **S** antibodies, in contrast to the Rh-Hr antibodies, generally fail to clump saline-suspended ficinated cells containing the specific blood factor. They also showed, in this patient, the presence of univalent **U** antibodies.

Wiener and Unger made an interesting observation regarding the number of antigenic sites per red cell in the M-N-S-U and the Rh-Hr systems.[229] They found a similar ratio between the antiglobulin titer and the blocking titer for **U** antibodies and for $\mathbf{Rh_0}$ antibodies suggesting that the number of antigenic sites per red cell are approximately equal for the 2 systems. Wiener and Unger also showed that there is evidence that the number of antigenic sites on the red cell surface for the **F** (**Duffy**) and **K** (**Kell**) factors is lower than for the M-N-S-U and Rh-Hr systems.[229]

Hu (Hunter) factor

In 1934 Landsteiner et al.[230] injected the blood of a Negroid (Mr. Hunter) into rabbits and obtained an antiserum that agglutinated the blood cells of 7.3% of Negroids and 0.5% of whites. The antigen was also found on the cells of 22% of West Africans; it is rare in Europeans. Wiener[231] found that all of the blood specimens that gave distinct positive reactions with this antiserum were type N or type MN, which suggested a relationship to the M-N system. Isoimmune antibodies in man have not as yet been reported.

He (Henshaw) factor

In an attempt to repeat the experiments which had resulted in finding the **Hu** factor, Chalmers et al.[232] injected the blood of a Nigerian (Mr. Henshaw) into a rabbit, with the resultant production of anti-**He** antibodies by the rabbit. The factor identified by the antiserum, **He**, has been found in 38 of 1390 West Africans or 2.7%, but it was not found in the blood of the 1500 Europeans tested. When most of the bloods positive for the **He** factor were found to have antigens **N** and **S** as well, it was shown to belong to the M-N-S system. Comparative tests with the original anti-**Hu** serum showed anti-**Hu** and anti-**He** to be different.

When **Hu** or **He** is associated with factor **M** in the parents, there is a similar association in the children. As Wiener and Wexler pointed out,[214] this indicates that **Hu** and **He** do not represent attributes of separate substances but together with **M, N, S,** s, and **U,** as the case may be, are factors of one and the same agglutinogen. No natural or isoimmune antibodies of the nature **He** have been found to date in human beings. See M^e, p. 1551.

Tests for M and N factors in blood cells

Blood for M and N tests may be collected in dry tubes such as those used in the Wassermann test, in tubes containing dried oxalate powder (p. 1463), or by mixing the blood with ACD* solution in the proportion of 4 parts blood to 1 part ACD. Venous blood is preferred, and blood taken in dry oxalate is most satisfactory not only for the M-N tests but also for the A-B-O and Rh tests. In infants or in patients with small or inaccessible veins, an adequate sample for blood grouping tests can usually be obtained from a deep puncture of the heel or of one of the fingers, after the hand has been immersed in hot water to produce hyperemia. Finger blood is collected in small tubes, inside diameter 7-8 mm., containing a few drops of ACD solution, in the proportion of 5-10 drops blood to 1 drop ACD solution.

Procedure:

1. Prepare a fresh 2% cell suspension in saline of the unknown bloods.
2. Using a welled or ceramic slide, place 1 drop of blood cell suspension to be tested in each of 2 wells.
3. Add 1 drop of anti-**M** serum to the left-hand ring and 1 drop of anti-**N** serum to the right-hand ring. The drops should fill the wells.
4. Place the slide on a rotating machine or rotate by hand for 10 min.
5. Take readings macroscopically and under the low power of a microscope and interpret as in Table 340.

In positive reactions the clumps are large and easily visible to the naked eye, whereas microscopically the agglutination is complete with few free cells between the clumps.

In negative reactions the suspension remains homogeneous, and upon microscopic examination each cell is separate and distinct.

Occasionally bloods will show partial agglutination, that is, large clumps on a background of free cells; in all such cases it should be possible to elicit a history of recent blood transfusion, showing a mixture of 2 different M and N types of cells in the individual's circulation.

Controls: Controls are made at the same time as the test, using known M, N, and MN cell suspensions against the anti-**M** and anti-**N** sera. These are handled just like the tests. Possible results are given in Table 341.

If any other results are obtained with the controls, the cause must be determined and new antisera tested. The unknown bloods then should be tested with the new antisera.

Sources of error in M and N testing technic: False negative reactions may result when old blood suspensions are tested, particularly when using anti-**N** serum. This is avoided by using only fresh blood.

False positive reactions may occur if the tests are held too long and drying occurs.

Anti-**M** serum agglutinates all blood containing the M agglutinogen (types M and MN), whereas anti-**N** serum agglutinates all

blood containing the N agglutinogen (types N and MN). To date no proved case has been found with blood not reacting with either anti-**M** or anti-**N** serum. Note that, theoretically, if the hypothetical M^gM^g individual exists and is ever found, such blood may fail to react with both anti-**M** and anti-**N** sera.

Production of anti-M and anti-N sera—Wiener[231, 233]

In order to prepare anti-**M** and anti-**N** sera by immunizing rabbits, it is necessary to procure a number of types OM* and ON donors. All sterile precautions must be observed throughout the procedure.

1. Withdraw 50 ml. type OM and 50 ml. type ON blood directly into their respective 50 ml. Rockefeller centrifuge tubes, each containing 4 ml. of sterile 3.8% sodium citrate solution. Shake to prevent clotting. It is best to pool blood from several OM donors and to do likewise with blood of several ON donors.
2. Wash with sterile saline several times until all plasma has been removed. This prevents possible anaphylaxis and production of antibodies for human serum globulin in the rabbits. Restore to original volume.
3. Add 12 ml. of this blood to 48 ml. saline to provide sufficient material to inject 4 rabbits 6 times each. Keep the blood refrigerated when not in use.
4. Use 4 rabbits† for anti-**M** and 4 for anti-**N** production. Each rabbit must be identified with an ear tag, and complete records must be kept. Inject 2 ml. OM blood into the marginal ear vein of each anti-**M** rabbit and 2 ml. ON blood into the marginal ear vein of each anti-**N** rabbit.
5. Repeat the injections daily for 6 days.
6. Allow 1 wk. rest interval; then repeat the 6 injections, giving the first intramuscularly and the other 5 intravenously. Giving the first injection intramuscularly prevents anaphylaxis and possible agglutination of the injected cells and death of the rabbit.
7. Allow another rest interval of 1 wk.; then repeat the 6 injections, giving the first injection intramuscularly and the other 5 intravenously.
8. Wait another week and test to determine whether anti-**M** or anti-**N** agglutinins have been produced in any of the animals. The entire period of injections and intervals covers 6 wk.

Tests must be made of the serum of each injected rabbit before withdrawing all its blood to be used as a laboratory reagent.

Preliminary tests of immunized rabbit serum for M and N antibodies:

1. Withdraw 2 ml. blood from the ear vein of each rabbit; place in a clean, dry, sterile Kahn tube properly labeled with the type letter and the identifying number of the rabbit from which the blood has been withdrawn.
2. Allow to clot, loosen the clot, centrifuge, remove the supernatant serum, and place it in a clean, dry, sterile Kahn tube properly labeled.
3. Inactivate the serum for 30 min. at 56° C. to destroy the complement and prevent subsequent hemolysis.

Since the sera of immunized rabbits contain species agglutinins, it is necessary to remove these before any tests can be performed. These are removed by absorption.

To absorb anti-**M** serum, pooled groups ON, AN, and BN cells are added to the rabbit serum. To absorb anti-**N** serum, pooled groups OM, AM, and BM cells are added to the rabbit serum. The anti-**M** serum is not easily overabsorbed, but the anti-**N** serum is, and therefore great care must be used in absorbing anti-**N** serum.

Absorptions are usually carried out at room temperature, using sufficient quantities of absorbing cells to ensure complete removal of the species antibodies. If the absorptions are carried out at lower temperatures, smaller amounts of blood cells are required.

1. Dilute the antiserum 1:20 by adding 2 drops of serum to 38 drops of saline.
2. Place 1 ml. diluted serum in a Kahn tube.
3. Add 0.5 ml. of washed cells of correct specificity to the serum. If preparing anti-**M** serum, use N cells; if preparing anti-**N** serum, use M cells.
4. Mix thoroughly, allow to stand 30 min. at room temperature, centrifuge, and use the supernatant fluid. In preparing anti-**N** serum,

---

*Group O. type M.

†Four rabbits are used because some might fail to develop sufficient antibodies.

place the tube in a glass of warm water in an incubator at 37° C. for 30 min., then centrifuge, and use the supernatant fluid.

5. Test each serum against several specimens of M, N, and MN bloods.
6. On a slide containing 3 wax rings, properly labeled, place 1 drop of type M cells in the first ring, 1 drop of type N cells in the second ring, and 1 drop of type MN cells in the third ring. These are 2% suspensions in saline.
7. Add 1 drop of anti-**M** testing fluid to each ring.
8. Rotate and examine periodically under the low power of a microscope for 7-10 min.
9. Prepare a similar slide, using anti-**N** instead of anti-**M** testing fluid.

If the anti-**M** fluid agglutinates all M and MN cells within 1 or 2 min. but fails to agglutinate N cells after 10 min., it is then titrated for antibody content.

If the anti-**N** fluid agglutinates all N and MN cells within 1 or 2 min. but fails to agglutinate M cells within 7-10 min., it is then titrated for antibody content.

If the anti-**M** fluid agglutinates N cells or if the anti-**N** serum agglutinates M cells, the serum must be reabsorbed, care being taken not to overabsorb. If the **anti-**M serum now fails to agglutinate M cells or if the anti-**N** serum fails to agglutinate N cells, the serum cannot be used.

Titrate each fluid, using the technic on p. 1476. The anti-**M** fluid should have a minimum titer of 10-20 units and the anti-**N** fluid a minimum titer of 5-10 units.

Collection of anti-M and anti-N testing fluids: Having selected the rabbits that show agglutinin anti-**M** in a titer of at least 10 and anti-**N** in a titer of at least 5-10, exsanguinate by severing the carotid artery, using utmost sterile precautions, and obtaining the entire content of blood from each animal. For the method of bleeding rabbits from the carotid artery, refer to p. 808.

1. Collect the blood in clean, dry, sterile 50 ml. Rockefeller centrifuge tubes, properly labeled. Cork immediately and allow to clot with the tubes in a slanting position.
2. Refrigerate for 24 hr., strike the tubes against the palm of the hand to loosen the clot, and then centrifuge at high speed for 15-30 min. to separate the serum from the clot.
3. Under sterile conditions withdraw the serum and place it in sterile 20 ml. test tubes, properly labeled and stoppered with cotton.
4. Inactivate at 56° C. for 30 min.
5. Retain a few ml. for absorption.
6. Ampule the remaining serum, labeling with the rabbit's identification number, the type letter, date, and the notation "Inactivated, unabsorbed."

The serum will remain in good condition for a longer period if left unabsorbed. Absorb only enough for several months' use.

Absorption of anti-M serum:

1. Using all sterile precautions, dilute the serum 1:20 with sterile saline.
2. Place 10 ml. diluted serum in one tube and 10 ml. in another.
3. Place 5 ml. of washed, packed, pooled group ON, AN, and BN cells in each anti-**M** diluted serum.
4. Cork the tubes and mix by inverting back and forth about 6 times; then allow to stand for 30 min.
5. Centrifuge and test for the presence of anti-**M** or anti-**N** agglutinins as described above. Carry out the absorption at room temperature. Absorption is complete in the case of anti-**M** fluids when there is no longer a reaction with type N bloods, while the serum still agglutinates types M and MN cells within a 1 or 2 min. period.

Absorption of anti-N serum: Great care must be exercised not to overabsorb the serum. Carry out the absorption slowly to approach the end point of complete absorption very accurately.

1. Use groups OM, AM, and BM pooled, washed, packed cells to absorb the anti-**N** serum, adding the cells to the diluted serum as with anti-**M** absorption.
2. Keep the mixture of anti-**N** fluid and type M cells in a glass of warm water at 37° C. in an incubator for 30 min.
3. Then remove from the incubator and test. If the antiserum has not been completely absorbed, add more cells, using only half the above quantity, and repeat the same technic in the incubator.

This serum must agglutinate types N and MN cells within 1 or 2 min. but must not agglutinate type M cells within a 10-20 min. period.

Assuming that the M cells are not agglutinated by the anti-**N** serum and the N cells are not agglutinated by the anti-**M** serum, but each antiserum clumps its specific cells, the 2 products may be bottled. Some laboratories add a small amount of Merthiolate, 1 part of 1% solution to 100 parts of testing fluid to give a 1:10,000 concentration, to prevent growth of bacteria.

Levine[234] recommended toluol as a preservative for anti-**M** and anti-**N** agglutinins in testing fluids. Add 1 drop of toluol to each ml. of diagnostic fluid. Stopper and seal with paraffin. After 32 mo. Levine found that the anti-**M** was just as active as when freshly prepared. The best way to preserve antisera is in the frozen state without the addition of any chemical.

In working with anti-**M** and anti-**N** testing fluids, as shown by Landsteiner and Levine, bloods containing factor **N** alone are more strongly agglutinated by anti-**N** testing fluids than bloods containing **M** and **N** together. Type N blood is about twice as sensitive as type MN blood to agglutination with anti-**N** serum.[233] It must be emphasized that control bloods of all 3 types are necessary in the performance of M and N tests. Wiener emphasized that, in a large experience, using 3 different anti-**M** fluids and 3 different anti-**N** fluids, he had never found a discrepancy among the reactions. However, with the recent discovery of the M^e factor, this is no longer true (p. 1551).

There are certain sources of error in the preparation of these antisera, which Wiener has outlined. First, great care must be used in the preparation of anti-**M** and anti-**N** testing fluids. Overabsorption is the fault of most beginners in making these fluids. Wiener has shown that there may be interfering reactions caused by specific agglutinins other than those directed against M and N. Similar interfering reactions may be caused by natural or immune agglutinins against A and B, and there may be coexistence in the same serum of more than one of the agglutinins against M and N. To obviate these difficulties, the preparation of the testing fluid by absorption should be carried out by using a mixture of bloods of types OM, AM, and BM. Again Wiener has shown that there is danger of false positive reactions from underabsorption of the immune sera. This particularly applies to the tests for **N** but may be prevented easily by the inclusion of negative control bloods.

LUTHERAN BLOOD SYSTEM

Blood group factor Lu

Callender et al.[235] reported an antibody, later described in more detail by Callender and Race in 1946,[236] found in the serum of a patient with disseminated lupus erythematosus; this patient had received a number of blood transfusions and produced a number of isoimmune antibodies. The name of the donor was Lutheran, and the antibody was designated anti-**Lutheran.** The antigen, at first called **Lutheran,** could not be given the designation "L" because of possible conflict with the **Lewis** antigen. The term **Lu** was later used to designate this antigen. Later the notations $\mathbf{Lu^a}$ and $\mathbf{Lu^b}$ were agreed upon for the antigen and its reciprocally related factor. The phenotypes are described as Lu(a+) and Lu(a–). The corresponding antibodies are anti-$\mathbf{Lu^a}$ and anti-$\mathbf{Lu^b}$. Anti-$\mathbf{Lu^b}$ was discovered by Cutbush and Chanarin[237] in 1956 and by Greenwalt and Sasaki[238] in 1957. $\mathbf{Lu^a}$ was shown by Callender and Race to be inherited as a mendelian dominant.

The incidence of Lu(a+) was found to be 6.93%. Wiener[214] states that if heredity by a pair of allelic genes Lu^a and Lu^b is postulated, the genotype frequencies calculated from these data are Lu^aLu^a, 0.12%; Lu^aLu^b, 6.81%; and Lu^bLu^b, 93.07%.

The antibodies for $\mathbf{Lu^b}$ have been found after isoimmunization during pregnancy and as a result of a blood transfusion.

J-j SYSTEM—KIDD BLOOD GROUPS (ALSO CALLED Jk^a AND Jk^b)

In 1951 Allen et al.[239] described an antibody, in the serum of a mother of an erythroblastotic baby, which was found to be serologically independent of the other blood systems. The patient in whom the antibody was found was named Kidd, which gave the designation **Kidd** to the antigen identified by the new antibody. Since the Kell-Celano system had already utilized the K-k symbols, the designation Kidd was later changed to $\mathbf{Jk^a}$, and when the reciprocal factor was found, it was called $\mathbf{Jk^b}$. These terms were later changed to **J** for $\mathbf{Jk^a}$ and **j** for $\mathbf{Jk^b}$.

The reciprocal antibody, anti-$\mathbf{Jk^b}$, was found in 1953 by Plaut et al.[240]

The incidence of factor **J** is approximately 75-77% among Caucasoids; among Negroids it is 90%, and among Mongoloids it ranges from 50-100%.

Identification of factors **J** and **j** are made by the use of anti-**J** sera, using the antiglobulin technic, since other tests usually fail to detect the antigen. The tests for these factors, therefore, have the same limitations as do the Duffy tests. Moreover, the antisera tend to lose their activity upon storage so that the tests must be repeated several times, using Wiener's blind technic, and including controls of known types J and j. Anti-**j** serum is not as yet easily available.

Testing for J factor

1. Wash the unknown cells 3 times in saline and resuspend to a 2 or 3% suspension. These cells are **not** to be enzyme-treated.
2. Place 1 drop of the cell suspension in a small tube (7 mm. inside diameter) and add 1 drop of anti-**J** serum.
3. Prepare positive and negative control cells and treat in the same manner.
4. Place in a water bath at 37° C. for 1 hr.
5. Read the sediment macroscopically and under a scanning lens.
6. If the reactions are negative (as they probably will be since the **J-j** factors require antiglobulin tests for their detection), wash 3 times in saline and remove all traces of saline after the last washing. Turn the tubes upside down and strike the lip hard against a gauze sponge after the last washing.
7. Add 1 drop of antiglobulin serum (Coombs), mix, and centrifuge at 500-1000 r.p.m. for 1 min.
8. Gently dislodge the sediment and read as before.

If the positive and negative controls give correct readings, then agglutination means the presence of factor **J** and lack of agglutination indicates its absence.

DIEGO BLOOD SYSTEM—FACTOR Di

Levine et al.[241] found an antibody in the serum of a mother of an erythroblastotic baby, which identified blood factors serologically distinguishable from those of other known blood group systems. The family name was Diego, and the antigen identified by the antibody became known as the **Diego** or **Di** factor. It seems to be common among South American Indians but was not found in tests on 2600 consecutive Caucasoid blood specimens.[242] Layrisse and Arends,[243] in a series of tests, found the **Di** factor to be common among Chinese, Japanese, pure-blood Negroes, North American Indians (incidence 2-45%), Eskimos, and Polynesians. The inheritance of the **Di** factor has been confirmed as a simple mendelian dominant. It has been found in 4 generations of a single family.

OTHER BLOOD GROUP FACTORS—HIGH- AND LOW-FREQUENCY FACTORS

Some authors use the term "public antigens" to refer to high-frequency factors, those possessed by the vast majority of people. Since we prefer the term "high-frequency" factors, it will be used here.

Some high-frequency factors are blood factor **H** of the A-B-O system, **U** of the M-N-S-U system, **hr″** of the Rh-Hr system, **Tj**^{a} of the P system, and factors **k** and **Kp**^{b} of the K-k (Kell-Cellano) system. Four other high-frequency factors are **Vel**, **Yt**^{a}, **I**, and **Sm**.

High-frequency blood factors

(1) **Blood factor Vel:** In 1952 Sussman and Miller[244] tested the serum of a patient who had had a transfusion reaction, against 10,000 samples of group O blood, and found that all but 4 of these were agglutinated by the serum. Since the patient's name was Vel, the antibody in the blood was called anti-**Vel**. Levine and associates reported a second example of anti-**Vel** and showed it to be different from anti-**Tj**^{a}, anti-**U**, and anti-**H**.

The Vel factor has a frequency of 99.96%, so that negatively reacting bloods are extremely rare. No naturally occurring anti-**Vel** antibodies have been reported, and isoimmune antibodies have been found only rarely.

The anti-**Vel** of Sussman and Miller clumped incompatible red cells suspended in saline but with a titer of only 4 units, although the titer was 32 units in plasma medium. The patient gave a history of previous pregnancies and transfusions, to which her isosensitization could be ascribed. Sussman and Miller carried out tests on relatives of the patient and on those of the 4 **Vel**-negative donors whom they found, but each of the 8 siblings proved to be **Vel** positive. On the plausible assumption that **Vel**-negative individuals are homozygous, genotype *vv* for a rare gene, the frequency of this gene *(v)* was calculated to be approximately 2% and that of its allele *(V)*, 98%.

A second case of sensitization to the **Vel** factor was reported in 1955 by Levine et al.[245] This was a woman who had had previous pregnancies and transfusions which could have sensitized her. Cross-matching tests carried out preliminary to another transfusion proved every one of 1000 successive random donors incompatible. Unlike the original serum of Sussman and Miller, however, the freshly drawn serum of the second patient caused hemolysis of all red cells tested, whereas the patient's inactivated serum caused agglutination. The patient's red cells were tested with the original anti-**Vel** serum and proved to be Vel negative, and the antibody in her serum was shown to correspond to anti-**Vel**.

A third case of **Vel** sensitization was reported in 1959 by Bradish and Shields[246] in a male patient who had been sensitized by transfusions, and the serum reacted like that of the patient described by Levine. Higher titers were obtained in plasma medium than in saline medium, and the serum also reacted by the indirect antiglobulin technic.

Recently (1961) Levine et al.[247] described another sensitized **Vel**-negative individual who had had a hemolytic transfusion. Her antibody produced both hemolysis and agglutination. Family studies disclosed 7 Vel-negative persons in 3 generations.

Strickel et al.[248] described 2 sisters who both lacked the **Vel** factor. Wiener et al. in 1961[249] described still another case of **Vel** sensitization discovered in the course of routine cross-matching tests preliminary to blood transfusion. Tests were also carried out on relatives of the patient in a search for compatible donors. The patient was group O MN k Rh_2rh. Every group O Rh-positive blood was incompatible with her serum, which hemolyzed the cells, although hemolysis was only about 5-50%. In titrations, hemolysis was observed in saline dilutions of her serum up to 1:4 but not in higher dilution. The antiglobulin test was made after washing the unlysed cells in saline 3 times; clumping occurred. The antibody titer by the antiglobulin technic was 30 units. Ficinated cells were also lysed by the patient's unheated serum, and this was more pronounced than with the unmodified cells. Her serum did not hemolyze or agglutinate her own red blood cells. The direct antiglobulin test was negative. She was not autosensitized.

Tests with 200 donors yielded no compatible bloods. She was type k and **hr″** positive, which ruled out possibility of sensitization to these 2 factors. The behavior of the antibody did not correspond to that which is characteristic of **hr″** or **Kell** antibodies. She was U and **I** positive as well as **H** positive. By using anti-**Vel** serum it was shown that she was **Vel** negative. Laboratory tests showed that this patient had no autosensitization.

The problem of transfusing a sensitized **Vel**-negative individual is very difficult to resolve. The simplest answer is prevention of sensitization. Since **Vel**-negative persons are possibly or probably homozygous for a rare recessive gene, whenever such a person is found all siblings should be tested. If any should prove to be **Vel** negative, he should be so informed and given a suitable identification card warning that no transfusions be given except in dire emergency. If transfusion is essential and time permits, one of his siblings known to be **Vel** negative and compatible should be selected as a donor in order to avoid sensitization. Once sensitization has occurred, obviously no transfusion is entirely safe unless a **Vel**-negative donor is used. Where there are no **Vel**-negative siblings, a central clearinghouse at which the names and addresses of donors of rare blood types are kept on file may supply the blood. The central clearinghouse of the American Association of Blood Banks lists 12 **Vel**-negative donors.

When no **Vel**-negative blood is available, Wiener and associates suggest that the patient may be a donor for himself. For example, in the case of cardiac or other elective surgery which may be scheduled months in advance, the patient can be bled periodically and his blood frozen or stored in ACD solution in a refrigerator, depending on the circumstances; then when the patient is subjected to surgery, his own blood can be used as needed.

(2) **Blood factor Yt^a:** In 1956 Eaton et al.[250] described an antibody, anti-**Yt^a**, which reacted with the great majority of blood cells tested. The patient had had several transfusions before the presence of anti-**Yt^a** was found in an incompatible cross matching. It reacted with a modification of the indirect antiglobulin test and with the trypsin antiglobulin test. It was found to be unrelated to the other known blood group systems. Another example of isosensitization to **Yt^a** was later found.[181] It must be pointed out that only those who lack the factor can form the antibodies, and the scarcity of isosensitization shows the almost universal nature of the factor **Yt^a**.

(3) **Blood factor I:** In 1956 Wiener et al.[251] reported their finding of an isoantibody of high titer in the serum of a group A_1B woman with acquired hemolytic anemia, which proved to be of the cold antibody type. Her serum also showed another isoantibody, reactive at room temperature with almost all other human blood cells but not with the patient's own cells. The factor detected by this patient's serum proved to be different from all other previously found blood factors. Because of the high degree of individuality of blood specimens which failed to react with the patient's antibody at room temperature, the antibody was designated anti-**I**, and the antigen it identified was called **I**. Further examples of the same antibody have been reported in 3 environments[252]: (a) anti-**I** in the serum of patients with acquired hemolytic anemia of the cold antibody type, of which there were 9 examples; (b) anti-**I** in sera which in the past had been said to contain a "nonspecific complete cold autoagglutinin," of which there are more than 50 reported incidents[253]; and (c) anti-**I** in the sera of normal persons whose red cells have abnormally little **I** antigen. There are 6 examples of this. Shapiro found a case of anti-**I** in South Africa.[254]

Wiener designated those persons whose blood contained the factor as I and those who lacked it as i (**I** negative). Among a series of 22,964 random donors, only 5 proved to be **I** negative, and 4 of these were Negroids. The **I** antigen is very feebly developed at birth.

Variants of the I agglutinogen have been suggested because of the markedly different titers which were obtained against different cells, ranging from 25 to 5000 units—I_1, I_2, I_3, etc., and i.

W. Weiner et al.[255] demonstrated in 1959 that 2 of their patients with acquired hemolytic anemia of the cold antibody type had the antigen **I** on their red cells and anti-**I** in their serum. The autoantibodies of patients with acquired hemolytic anemia of the warm antibody type can often be shown to be specific for known blood group antigens possessed by the patients. It has now been shown that some patients with acquired hemolytic anemia of the cold antibody type have the **I** antigen on their cells and anti-**I** in their serum.

(4) **Blood factor Sm:** Schmidt et al.[255a] reported a new antibody, anti-**Sm**, in the serum of a mother apparently immunized by pregnancy.

Low-frequency blood factors

Low-frequency blood factors have been called "private" blood factors by some investigators since they seem to occur only in particular families. A number of such low-frequency antigens have been found: **Mi** and **Gr** of the M-N-S-U system, **rh**^{w}, **rh**^{w2} and **rh**^{x} of the Rh-Hr system, and **Kp**^{a} of the K-k system. In addition to these, there are the **Leavy, Jobbins, Becker, Ven, Be**^{a}**, Ca,*** **Rm,** and **By** factors. Most of these have been found in hemolytic disease, some were stimulated by pregnancy, and some were stimulated by transfusion. These antigens are distinguishable by specific antisera and are independent of the 9 blood group systems.

With all the factors, positively reacting bloods are very rare. No naturally occurring isoantibodies have been reported to date, and isoimmune antibodies are very rare.

Factor Ca

Wiener and Brancato[256] described the results of their studies on a rare hereditable human agglutinogen discovered during the study of a puzzling case of erythroblastosis fetalis. This baby and her mother were both Rh negative, and no A-B-O blood group incompatibility could be demonstrated. The problem of specificity of the antibody remained unsolved for 8 yr. until newer and more sensitive methods for detecting antibodies were devised, the antiglobulin and enzyme technics. At that time it was possible to demonstrate in the mother's serum, in addition to an **Rh**$_{o}$ antibody, an antibody for a second blood factor present in the child's blood cells. The factor was given the designation **Ca** from the family name (Cavaliere). This factor was not found in blood cells of 48 consecutive type rh bloods taken at random but was present in 4 out of 7 type rh individuals in the patient's own family. No **Rh**$_{o}$ variant was demonstrable in the patient's cells.

The **Ca** factor seems to be a rare hereditable blood factor probably independent of Rh-Hr types.

Factor Xg and a sex-linked blood group

In 1962 Mann et al.[257] described the first sex-linked blood group antigen, designating it as **Xg**^{a}, the new antibody as anti-**Xg**^{a}, the phenotypes as Xg(a+) and Xg(a–), the gene responsible for the antigen as Xg^{a}, and the gene for its so far silent allele as Xg. Random tests of 342 Caucasians showed the following distribution:

Of the females 88.83% were positive, and of the males 61-69% were positive. The difference is overwhelmingly significant ($\chi^2 = 34.8$ for 1 d.f.).

Xg(a+) males are of the genotype $Xg^{a}Y$, and Xg(a–) males are of the genotype $Xg\ Y$. Xg(a–) females are of the genotype $Xg\ Xg$.

The authors compared the expected distribution of the Xg groups in Caucasian parents and offspring with the results actually observed in testing 50 Caucasian families with 104 children. Details of the families illustrate very clearly certain rules which may be laid down for an X-borne dominant antigen:

1. From the mating positive × positive, there can be no negative daughters; only sons may be negative, which is the most striking feature in this situation.
2. From the mating positive male × negative female, all sons have to be negative and all daughters positive, with which the present findings conform.
3. From the mating negative male × positive female, all sorts of children are possible, and all sorts have been found.

Other rules, corollary to these, are as follows: of positive men, the mothers and daughters must be positive; of negative women, the fathers and sons must be negative. To these rules the families also conform, as do the members of 25 families lacking one parent. These rules apply to ordinary males and females and need not necessarily apply to people with Turner's syndrome (XO) or with Klinefelter's syndrome (XXY).

There is little reason to hope that another example of the antibody will be found for years, because innumerable Xg(a–) persons must have been transfused with Xg(a+) blood; yet until now no one is known to have produced the antibody. This statement has been amended by Mann et al. (see below).

***Wr**^{a} is omitted from this list because it has been shown to be the same as Wiener and Brancato's earlier described **Ca** factor.

A second example of anti-**Xg**^{a} has been reported (1963) by Cook et al.,[257a] which, like the first, could be detected only by the antiglobulin test, and this antiglobulin serum must contain either an adequate amount of anti-β_1 (complement) globulin or an exceptionally large amount of anti-7S gamma globulin. As tests for the antibody improve there is little doubt that other examples will be found.

The antigen is well developed at birth, 8 out of 12 cord samples having been found to be Xg(a+); and of 4 fetal samples 2 were Xg(a+) and 2 were Xg(a–).

The number of Negroes so far tested are few, but the studies made of these few suggest that the distribution of the antigen is about the same as that in Caucasians. Tests on 61 New York and West Indian Negroes showed 26 males and 15 females as Xg(a+) and 18 males and 2 females as Xg(a–).

Mann and associates believe that the antigen may play a leading role in helping to plot the relative position of genes on the X chromosome. In collaboration with many other experts, they are beginning to test families with red-green color blindness, hemophilia, Duchenne's type of muscular dystrophy, glucose-6-phosphate dehydrogenase deficiency (G-6-PD), and other, rarer characters known to be controlled by X-borne genes. If the Xg locus is close to the hemophilia or to the Duchenne locus, then in some families it would be possible to distinguish normal women from carriers with an error in proportion to the recombination frequency. The Xg groups should be of aid in mapping the X chromosome and in problems of dosage compensation; they should be useful in certain families in attributing to oögenesis or to spermatogenesis the nondisjunction which is responsible for Turner's and Klinefelter's syndromes.

Chapter 79

Whole blood transfusions*

ADDINE G. ERSKINE

The transfusion of whole blood is accompanied by certain risks, such as unintentional transfusion of incompatible blood due to clerical errors, incorrect identification of the recipient (laboratory errors), as well as transmission of certain diseases, notably hepatitis (p. 1568). Transfusions should be undertaken only when clear-cut and substantial indications exist. Mild hemoglobin deficiencies can usually be corrected by satisfactory dietary intake and supplementary medication. Whole blood transfusions should be reserved for patients who are refractory to such treatment or in situations requiring immediate replacement of blood. Even emergency blood transfusions should never be attempted without proper laboratory preparations since plasma may be given without blood grouping tests and an osmotic pressure almost equal to that of whole blood can be obtained by the use of plasma or albumin.

Whole blood should be available at all times to prevent any delay necessitated by a search for donors. Although this compromises the freshness of the blood, the use of stored blood is essential (refer to blood banks, p. 1582). The blood requirements of most patients can usually be met by blood stored up to 21 days, but certain conditions require transfusion of fresh blood (less than 24 hr. old).

INDICATIONS FOR WHOLE BLOOD TRANSFUSIONS

Hemorrhage: The principal indication for transfusion of whole blood is sudden loss of blood from hemorrhage. Such cases call for immediate transfusion of whole blood. In addition to this acute blood loss, loss of blood in hemorrhagic diatheses requires replacement with whole blood. Two significant factors enter into the body's defense against hemorrhage[258]: (1) coagulability of the blood and (2) vascular response. Defective coagulating mechanisms are seen in hypoprothrombinemia, thrombocytopenia, hemophilia, and fibrinogenopenia. Plasma is used in preference to whole blood in peripheral circulatory failure or shock.

Surgery: The preoperative preparation and postoperative care of patients may require transfusions of whole blood when there is impaired nutrition, secondary anemia, or lowered resistance. In hypoproteinemias plasma is preferred over whole blood, or a better procedure is an initial injection of plasma followed by the injection of whole blood.

Anemias: In addition to the hemorrhagic states, transfusion of whole blood is necessary in anemias of blood loss or those with increased erythrocyte destruction of hereditary or acquired nature. The basic principle of blood transfusion utility in anemia is a replacement therapeutic procedure. The usefulness of transfusions in anemias due to increased destruction or excessive hemolysis is seen in the good results in familial hemolytic jaundice, sickle cell anemia, erythroblastosis, and many acute and chronic types, as well as in Cooley's anemia and others.

---

*We wish to express our thanks to the American Association of Blood Banks, Chicago, Ill., for permission to use parts of Chapter VI of their Technical methods and procedures, revised edition, 1960, in the preparation of this chapter.

Leukemias: Transfusions may be indicated in leukemia. No particularly brilliant results are seen in the chronic leukemias except, perhaps, relief of the associated anemia.

Leukopenia: In leukopenia the rationale for transfusion is only of a supportive nature. According to Doan,[259] transfusion is proper in neutropenic states because normal blood contains nucleotides which stimulate the formation of these neutrophilic cells. Transfusions have been used in agranulocytosis with varying success in different hands.

Infections and poisonings: Blood transfusions are used in many acute and chronic infections and in other intoxications and poisonings. Plasma injections, however, have been even more useful.

CONTRAINDICATIONS FOR BLOOD TRANSFUSIONS

Contraindications for whole blood transfusions are principally acute pulmonary edema, cardiac decompensation, and massive pulmonary embolism or infarction.

HEPARIN AND TRANSFUSION

The Scandinavians have been using heparinized blood in transfusions for a number of years. It eliminates the disadvantages of sodium citrate as an anticoagulant and greatly simplifies the procedure of transfusion.

REQUIREMENTS FOR FRESHLY DRAWN BLOOD

Bleeding due to disorders in the clotting mechanism

Hemophilia: Since the antihemophilic factor of plasma is labile, blood for hemophiliacs should be as fresh as possible. Fresh frozen plasma, antihemophilic globulin, or dried plasma prepared from fresh blood may be used.

Afibrinogenemia: In many cases administration of commercially available purified fibrinogen is preferable to whole blood.

Hypoprothrombinemia: Prothrombin is also labile. Hypoprothrombinemia is usually present in jaundiced patients and in patients under Dicumarol therapy. (Some authorities believe that bank blood retains a high level of prothrombin for at least 1 wk.)

Thrombocytopenic purpura: Platelets, the corrective factor of blood in thrombocytopenic purpura, are labile and are most viable within 4 hr. after withdrawal of the blood. Some of the lability of the platelets may perhaps be overcome by the use of plastic bags or siliconed bottles for blood withdrawal, by the use of plastic tubing, and by coating with nonwetting agents those surfaces that come in contact with the blood, although the age of the blood is more important than the container. In some cases, however, substances supplied by the platelets are all that are necessary, and viable intact platelets are not needed.

Hypoplastic anemias

The longer the transfused red cells remain alive in the patient's blood stream following transfusions in patients with hypoplastic anemia, the more benefit such patients derive from transfusions. This is especially true of those patients who require large amounts of blood.

Erythroblastosis fetalis

In erythroblastosis fetalis the need is for long-lasting compatible red blood cells. The liver of a newborn infant is often unable to excrete the pigment resulting from breakdown of old transfused cells, and use of stored blood may make the pre-existing jaundice worse. In addition, for a period of several weeks the baby's bone marrow may fail to produce enough red cells to keep pace with the normal rate of destruction so that the transfused cells must carry the baby through this period.

Erythroblastosis fetalis due to Rh incompatibility: Opinions differ on the A-B-O blood group that should be given to erythroblastotic babies of groups A, B, or AB. Some use only low titer group O blood to which 1 or 2 vials of group A and group B group-specific substances are added. Table 343[260] shows how to select the proper blood group[261] if group O blood is not to be used routinely. Still others use group O blood after sedimentation of the red cells and removal of the plasma. Some use group O cells to which AB plasma has been added. Bank blood, regardless of its age, is better than no blood at all. Unger uses group O blood from which the plasma has been removed. He **never** uses group A and group B substances. In his opinion the only alternative is to use blood compatible with the mother's blood. Even if group O blood is used, it should be cross matched with the mother's blood and the major cross match **must** be compatible.

The Rh type of the blood used, usually Rh negative, must be compatible with the ma-

Table 343. *Selection of proper donor blood in exchange transfusions in Rh-Hr erythroblastosis**

Infant's group	*Mother's group*	*First choice of donor group*
A	A or AB	A
B	B or AB	B
AB	B	B
AB	A	A
AB	AB	AB

*From Wiener, A. S., Samwick, A. A., Morrison, H., and Cohen, L.: Exper. Med. & Surg. 11:276, 1953.

In all other instances use low titer group O blood or group O blood from which the plasma has been removed. By removing the plasma one knows that the titer of anti-**A** and anti-**B** is low.

ternal antibody as proved by suitable cross-matching tests. Always use Rh-negative blood if anti-**Rh**$_0$ is the cause of the erythroblastosis.

In an emergency, when the proper blood for the baby is not available, the mother's blood may be safely used despite its antibody content, according to many authorities, but if time and facilities are available, it is safer to remove the plasma and perhaps replace it with AB plasma, or wash her cells.

Erythroblastosis fetalis due to A-B-O incompatibility: The baby should receive low titer group O blood of the same Rh type as his own, i.e., Rh negative or Rh positive, or remove the plasma or wash the donor's cells.

Erythroblastosis fetalis due to an unidentified incompatibility: In these rare instances it is safe to use blood if the donor's cells are compatible with the mother's blood. The matching tests must include the antiglobulin method, and ficinated cell tests should also be made.

SMALL UNITS OF BLOOD

Small units of blood may be prepared by taking blood from the selected donor into several small containers at the time of donation. There are available small commercial evacuated bottles containing 15, 40, and 60 ml. ACD solution. The bottles are graduated so that the proper quantity of blood may be introduced into each bottle.

A Y-shaped plastic donor set suitable for drawing blood into several bottles is commercially available. Blood runs through the donor needle into a short length of plastic tubing; it then reaches a bifurcation where the tubing splits in two. On each end of the 2 lengths is a bottle needle. Each needle is inserted into a separate bottle. One bottle is filled while the tubing leading to the second is clamped off. When the first bottle is filled, its tubing is clamped shut and the second tubing unclamped. The first needle is then inserted into an empty bottle and so on, until the phlebotomy has been completed.

Some blood banks make a practice of keeping several small units of low titer group O Rh-negative blood for pediatric use.

EXTRACORPOREAL CIRCULATION

The increasing use of procedures involving circulation outside the body (extracorporeal circulation) during open-heart surgery has introduced new problems to the blood bank.

The following are points of difference from customary blood bank routine.

1. To ensure freshness, donations are made either on the afternoon before or the morning of contemplated use. Bloods drawn the day before are refrigerated.

2. To minimize hemolysis, donations are made (a) using the gravity method or (b) using nonwettable surfaces for collection and storage.

3. Blood is collected in a heparin solution in saline and used to prime the machine. The balance is collected in ACD solution. Since the heparin solution prevents clotting for only 24 hr., the blood must be used within this period or be discarded, unless it is collected in a double plastic bag, one with heparin and one with ACD; then the heparinized blood is transferred to the plastic bag with ACD, after which it has the usual 21-day expiration date.

4. To minimize other possible complications, (a) donors must fast for at least 4 hr. prior to donation, (b) blood must be mixed thoroughly during collection to prevent coagulation, and (c) blood grouping and cross-matching tests must be performed with meticulous care.

PACKED RED BLOOD CELLS

Avoid contamination in preparing packed cells.

Preparation of packed cells from blood collected in a bottle:

1. Collect the blood in a standard ACD anticoagulant solution.
2. Keep the blood refrigerated while the cells sediment or centrifuge the blood at 2000 r.p.m. for 60 min. after it has remained refrigerated for 24 hr.
3. Then remove the plasma within 48 hr. after collection. To do this, disinfect the rubber stopper in the blood bottle with tincture of iodine or other acceptable disinfecting solution.
4. Perforate the large free hole in the rubber

stopper using the needle attached to a sterile air filter; then insert a long plasma aspirating needle, taking care to keep the needle **above** the plasma surface. Insert the needle of the air filter through the **X mark** in the rubber stopper and not through the small free hole leading to the air vent tube.

5. Remove the supernatant plasma aseptically, aspirating it into a sterile evacuated bottle. Immediately remove the air filter to seal the bottle containing the cell sediment.

If the cells have not been centrifuged, they may be transfused without addition of resuspending fluid, especially if the cells are well shaken before administration and a needle no smaller than 18 gauge is used in the recipient set. If a resuspending fluid is desired, ½ vol. or more of physiologic saline is added to the packed cells just prior to their administration. If the blood is to be centrifuged, cross matching is carried out beforehand, since the pilot tubes must be removed from the bottle in order to centrifuge it.

Packed or resuspended red blood cells should not be accepted for credit if returned to the blood bank, and in no case may they be reissued to another patient.

If packed cells are prepared this way, they **must** be used within 24 hr. of the time of preparation, although preferably sooner.

Preparation of packed cells from blood collected in a plastic bag: Commercially available plastic bags are adaptable to the preparation of packed cells. The bag may be centrifuged if desired; an air filter is not necessary; a length of tubing is attached between the blood bag and another container; the plasma is "squeezed" out of the bag by pressure on its surface. The remaining packed cells may then be administered from the original container. Since this is a closed system, the date of expiration of the cells is the same as that of the blood from which they were prepared.

CHOICE OF DONORS

The choice of donors is very important. The proper blood group should be selected as determined by the tests described. In addition, the donor must be in good physical health and able to withstand the withdrawal of 500 ml. blood without injury to health. (Refer to the section on Red Cross requirements.)

Universal donors

The term universal donor is applied to all persons of group O because, although their sera contain anti-**A**, anti-**B**, and anti-**C** agglutinins, their cells are not agglutinable by anti-**A** agglutinin (present in group B serum) or by anti-**B** agglutinin (present in group A serum). Since group O cells contain neither A nor B agglutinogen, it was previously believed that transfusion of group O blood into any individual would result in a compatible transfusion. This has proved to be incorrect. If the antibody titer of group O serum is high and group O whole blood is transfused into an individual of group A, B, or AB, a reaction may take place. Such blood should be used only in a genuine emergency.

Group O serum often contains isohemolysins in addition to isoagglutinins, and these are even more dangerous than the isoagglutinins.

In order to use group O donors for patients in group A, B, or AB, the anti-**A** and anti-**B** titer of the donor's serum must be ascertained by titration (p. 1476), and only those group O donors whose antibody titer is low (below average) should be used. Better still is a quicker procedure advised by Unger, namely, remove the plasma. It must be stressed that the use of the universal donor principle is not recommended and in some cases has led to disastrous results.

Witebsky substance, or A-like and B-like blood group specific substance

The first study on isolation of an A-like blood group-specific substance was carried out by Brahn and Schiff,[262] Freudenberg et al.,[263] and Landsteiner,[264] who had first isolated an A specific carbohydrate-like substance from horse saliva in 1932. Others have determined the chemical nature of the substances. An A-like blood group-specific substance occurs in relatively large amounts in commercial preparations of pepsin and peptone. Witebsky and Klendshoj[265, 266] isolated a B-like blood-specific substance from the stomach juice of group B subjects, using a method similar to that in which Goebel[267] isolated the A-like substance from commercial peptone. The B-like substance proved to be carbohydrate-like and was as potent as the carbohydrate-like A substance.

The presence of anti-**A** and anti-**B** isoagglutinins is at times ignored in the so-called universal group O blood plasma because of the dilution to which the serum of the donor is subjected in blood transfusions. When 500 ml. blood are given to adults in 1 blood transfusion, the resulting dilution is about 1:10. It is obvious, therefore, that blood plasma with high titers might be detrimental if introduced into the bloodstream of a patient of group A, B, or AB, particularly, according to Unger, if the patient has had a hemorrhage or is a child. It is, of course, likely that group substances in the blood as well as in the tissues capable of combining with isoantibodies represent a factor which, in addition to the dilution factor, is responsible for the fact that the isoantibodies in group O blood do not produce more damage than has been reported when group O is used as a universal donor, as noted by Wiener.[268]

Note: Unger calls attention to the fact that group O blood contains both bivalent and univalent antibodies, so that when titrations are made one must be sure to determine the titer of the univalent antibodies as well as of the bivalent antibodies. The univalent antibodies are not neutralized by group A and group B substances and are dangerous.

Witebsky found that the group A-like specific substance markedly inhibited the agglutination of human blood cells of group A by serum of group B. At a dilution of 1:250 his stock solution completely inhibited agglutination under his experimental conditions, whereas some inhibitory influence was detectable even in dilutions of 1 in several millions. Moreover, this substance was markedly heat stable when dissolved in saline. He also showed the lack of toxicity of this substance in work on guinea pigs. No agglutination of human red blood cells of group A by plasma of group O treated with group-specific substance occurred when the dilution of the plasma was as much as 1:256 or more. It is now believed that addition of the A-like blood group-specific substance to group O blood is effective in reducing the titer of the natural bivalent anti-**A** agglutinin in group O blood to an extent that renders this agglutinin practically ineffective. It must again be pointed out that this is true only of the bivalent and **not** the univalent antibody. It is **not** harmless and may stimulate immune antibodies in a female and be responsible for subsequent erythroblastosis.

Witebsky et al.[269] gave specific directions for preparation and transfusion of universal group O blood to patients outside the group. The Sanitary Code of the State of New York was amended and the amendment adopted by the Public Health Council on June 26, 1940, requiring that group O blood be titrated before it is used as universal blood and that no group O blood with high titers be permitted to be used for patients of other blood groups. Gesse[270] described 46 cases of hemolytic shock following transfusion of universal blood, 20 of which ended fatally.

The use of universal donor blood should be discontinued except in a real emergency when homologous blood is not available.
